Guidelines for interpreting listing criteria for species, populations and ecological communities under the NSW Biodiversity Conservation Act 2016

Version 2.0
NSW Threatened Species Scientific Committee, March 2018

The NSW Threatened Species Scientific Committee has prepared these guidelines to assist interpretation of the concepts and terms in the listing criteria given in the Biodiversity Conservation (BC) Regulation 2017. They should always be used in conjunction with the Biodiversity Conservation Act 2016 and the BC Regulation 2017. If cases arise where advice given in the guidelines is in apparent conflict with the Act or the Regulation, the Act and Regulation will apply.
Table of Contents

1 Introduction .................................................................................................................. 4

1 Introduction

The Biodiversity Conservation Regulation 2017 provides explicit criteria to guide listing decisions for threatened species, populations and ecological communities under the NSW Biodiversity Conservation (BC) Act 2016. The Biodiversity Conservation (BC) Regulation 2017 replaced the TSC Regulation 2010 after the NSW TSC Act was repealed by the Biodiversity Conservation Act 2016. To be eligible for listing as threatened, a species, population or ecological community must, in the opinion of the NSW Threatened Species Scientific Committee, meet one or more of the relevant Divisions specified in the Regulation.

Many aspects of the assessment and listing process under the BC Act are modelled on the IUCN Red List categories and criteria (IUCN 2001, Keith et al. 2013). Moreover, the listing criteria and the definitions of terms in the BC Regulation 2017 closely follow the wording of criteria and definitions in IUCN (IUCN 2001, 2017, Bland et al. 2017). These provide an explicit, objective and widely understood framework that represents international best practice for classifying species and ecological communities according to their extinction risk. The Red List criteria are a product of extensive consultation with a large community of international scientists and have undergone a long history of research, development and testing (Mace & Lande 1991, Mace et al. 2008). They are applied worldwide by an extensive network of specialists across all taxonomic groups excluding micro-organisms. Interpretation of the Red List criteria is supported by scientific advice from an international Standards and Petitions Working Group, which publishes and regularly updates detailed guidelines to assist application of the criteria across the full range of biological taxa (IUCN 2017, Bland et al. 2017).

The categories and criteria for listing species under the BC Act have a very close relationship with those developed for the IUCN Red List. The three categories of threat under the BC Act (Critically Endangered, Endangered and Vulnerable) mirror those used in the IUCN Red List for threatened species (IUCN 2001). The listing criteria and terms defined in the BC Regulation 2017 are also based closely on those developed by IUCN (2001). The criteria for listing ecological communities in the BC Regulation 2017 is comparable with the Red List Criteria for ecosystems (Keith et al. 2013). By adopting similar listing criteria, NSW benefits from this substantial intellectual capital associated with the IUCN Red List, ensuring world’s best-practice assessments of species, populations and ecological communities potentially at risk of extinction in NSW. The close parallels between listing criteria for the BC Act and the IUCN Red List also ensure a high degree of compatibility between listings in NSW and those on the global Red List.

The NSW Threatened Species Scientific Committee has prepared these guidelines to assist interpretation of the concepts and terms in the listing criteria given in the BC Regulation 2017. They draw extensively from relevant material in the IUCN Red List Guidelines (IUCN 2017, Bland et al. 2017). The BC listing guidelines address species, populations and ecological communities in separate sections, although cross-references are given where concepts and terms are common to these different entities. Where possible, examples are included to illustrate points of interpretation. The Committee intends to update these guidelines periodically to include additional examples and address new questions of interpretation as they arise. These guidelines should always be used in conjunction with the BC Act 2016 and the BC Regulation 2017.
arise where advice given in the guidelines is in apparent conflict with the Act or the Regulation, the Act and Regulation will apply.

2 Assessments of Species

Nominations of species for listing as threatened under the BC Act 2016 must be assessed under Division 4.1 of the BC Regulation 2017. A species is eligible for listing if it meets any one of the following clauses.

2.1 Clause 4.2 – reduction in population size

Clause 4.2 is based on IUCN (2001) criterion A. The basis for Clause 4.2 is the declining population paradigm (Caughley 1994): a declining population is more likely to become extinct than one that is stable or increasing (see also Mace & Lande 1991, Keith 1998, Mace et al. 2008, IUCN 2017). Species that have undergone large reductions or are likely to undergo large reductions in the future are likely to be at greater risk of extinction than those that have undergone or are likely to undergo smaller reductions. To be eligible for listing under Clause 4.2, species that have undergone a sufficiently large reduction within the relevant past time frame need not exhibit evidence of a continuing decline.

2.1.1 Reduction in population size

Reductions in population size refer to a decrease in the total number of individuals of the species in NSW over a specified time frame. Not all populations of a species may be changing at the same rate or in the same direction. To assess the overall reduction in the total population of a species, trends in local populations must be weighted according to their relative size and averaged. Thus, a species may not meet the criteria for reduction even though there is a very large reduction in one population, so long as the largest populations of the species are stable or increasing. Conversely, a species may meet the criteria for reduction if its largest population has undergone a large reduction, even though all other populations are stable or increasing. Where trends in all component populations of a species have not been estimated, a representative sample may be used to estimate any overall reduction in the total species population.

2.1.2 Measures of reduction

Clause 4.2 indicates that reductions in population size may be assessed in different ways according to Clause 4.2(2). Under Subclause 4.2(2a), direct observation refers to direct censusing or sampling of a species. Under Subclause 4.2(2b), an index of abundance appropriate to the taxon may include a range of direct or indirect measures including direct counts or estimates of all types of individuals, or direct counts of individuals belonging to particular life stages (e.g. mature individuals). Other indices that may be appropriate include projective cover of foliage or canopies, biomass, frequency of collections, observations or captures, harvest volumes, range size, area of suitable habitat, etc. Ideally, assessments of reduction should justify the choice of an appropriate index of abundance.

Under Subclause 4.2(2c), a reduction in population size may be based on a decline in the geographic distribution or habitat quality. Geographic distribution is defined under Clause 4.18 of the BC Regulation 2017 (see sections 2.2.1-2.2.2). Habitat quality (also known as habitat suitability) refers to the environmental conditions that
govern a species’ rates of survival, growth and reproduction, and hence the ability of its populations to persist. A reduction in habitat quality will therefore usually be associated with an increase in extinction risks due to a decline in survival, growth and/or reproduction. Where knowledge of the relationship between these demographic rates and the environment is limited, habitat quality may be inferred from variation in the abundance of the species across different environments. This type of inference requires careful evaluation because it assumes that populations will be in approximate equilibrium with their environment. Other habitat quality elements relevant to the consideration of reduction are habitat diversity and genetic diversity. Habitat diversity refers to the range of environmental conditions and resources that an organism is able to exploit to sustain its survival, growth and reproduction. A reduction in the range of available conditions or resources (e.g. resulting from loss of particular food sources or decline in types of nesting sites available) is likely to reduce the ability of a population to persist either as relics in habitat refuges or through behavioural adaptation to avoid adverse conditions and processes. Genetic diversity refers to the level of heritable (genetic) variation represented in the variety of alleles and genotypes within a species or population (Frankham et al. 2002). Genetic diversity may be structure between and within populations of a species and is usually measured by the frequencies of genotypes and alleles, the proportion of polymorphic loci, the observed and expected heterozygosity or the allelic diversity (Toro & Caballero 2005). A reduction in the genetic diversity may reduce the fitness of a species to persist in its present environment and reduce its evolutionary potential to adapt to environmental change.

In addition, a reduction in population size may be based on either (Subclause 4.2(2d)), the actual or potential levels of exploitation of the species, or (Subclause 4.2(2e)), a reduction in population size may be based on the effects of introduced taxa, hybridisation, pathogens, pollutants, competitors or parasites.

2.1.3 Magnitude of reductions
To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, a species must have undergone or be projected to undergo very large (Subclause 4.2(1a)), large (Subclause 4.2(1b)) or moderate (Subclause 4.2(1c)) reductions in population size. The corresponding listing criteria in IUCN (2001) provide indicative guidance for quantitative interpretation of these terms (Table 1). Past and projected reductions in population size may be interpreted under Subclauses 4.2(1a), 4.2(1b) and 4.2(1c) using more stringent numerical thresholds of criterion A1 (IUCN 2001) if the causes of reduction are clearly reversible AND understood AND ceased. If any of these conditions do not apply, the standard thresholds in criteria A2, A3 and A4 are appropriate (IUCN 2001).
Table 1. Corresponding thresholds for reductions in population size for the BC Regulation 2017 and the IUCN (2001) Red List criteria.

2.1.4 Time frames for assessing reductions

Reductions in population size must be assessed over a time frame appropriate to the life cycle and habitat characteristics of the taxon. Based on IUCN (2001), a time frame appropriate to the life cycle is three generation lengths or 10 years, whichever is the longer. For future declines the maximum period of assessment is 100 years, (IUCN 2017). Generation length is defined by IUCN (2001, 2017) (see Box 1). Note that age is calculated in a specific way following IUCN (2017) (see Box 1). In most cases, habitat characteristics will not alter the appropriate time frame determined from generation length. In exceptional circumstances, where an appropriate time frame for assessing reductions cannot be inferred from generation length, turnover in habitat may be used as a proxy for generation length. Usually, this will only be possible in taxa that have a direct life-history dependence on cyclical habitat dynamics (e.g. freshwater amphibians inhabiting ephemeral desert streams).

Box 1. Generation length

Definition of Generation Length (after IUCN 2001)

Generation length is the average age of parents of the current cohort (i.e. newborn individuals in the population). Generation length therefore reflects the turnover rate of breeding individuals in a population. Generation length is greater than the age at first breeding and less than the age of the oldest breeding individual, except in taxa that breed only once. Where generation length varies under threat, such as the exploitation of fishes, the more natural, i.e. pre-disturbance, generation length should be used.

Methods for estimating and inferring generation length (after IUCN 2017)

In general, time-based measures in the criteria are scaled for the different rates at which taxa survive and reproduce, and generation length is used to provide this scaling. The current definition of generation length has been widely misunderstood, and there are difficulties when dealing with very long-lived taxa, with taxa having age-related variation in fecundity and mortality, with variation in generation length under harvesting, with environmental changes and variation between the sexes. Some of the different acceptable methods for estimating generation length are included here.

It is also appropriate to extrapolate information such as a generation length from closely related well-known taxa and to apply it to lesser-known and potentially threatened taxa.

Formally, there are several definitions of generation length, including the one given above; mean age at which a cohort of newborns produce offspring; age at which 50% total reproductive output is achieved; mean age of parents in a population at the stable age
distribution; and time required for the population to increase by the replacement rate. All of these definitions of generation length require age- and sex-specific information on survival and fecundity, and are best calculated from a life table (e.g., option 1 below). Depending on the taxon concerned, other methods may provide a good approximation (e.g., options 2 and 3). Care should be taken to avoid estimates that may bias the generation length estimate in a non-precautionary way, usually by under-estimating it. Generation length may be estimated in a number of ways:

1. the average age of parents in the population, based on the equation
   \[ G = \frac{\sum x l_x m_x}{\sum l_x m_x} \]
   where the summations are from age \((x)\) 0 to the last age of reproduction; \(m_x\) is (proportional to) the fecundity at age \(x\); and \(l_x\) is survivorship up to age \(x\) (i.e., \(l_x = S_0 \cdot S_1 \cdots S_{x-1}\) where \(S\) is annual survival rate, and \(l_0 = 1\) by definition).
   This formula is implemented in an associated spreadsheet file (Generation length.xls, see IUCN 2017). To use this formula, follow the instructions in the file, noting the exact definitions of the parameters required.

2. 1/adult mortality + age of first reproduction. This approximation is useful if annual mortality after the age of first reproduction is well known, and if mortality and fecundity do not change with age after the age of first reproduction (i.e., there is no senescence). Many species exhibit senescence, with mortality increasing and fecundity decreasing with age; for these species, this formula will overestimate generation length (in such cases, use the spreadsheet mentioned above). For age of first reproduction, use the age at which individuals first produce offspring in the wild (which may be later than when they are biologically capable of breeding), averaged over all individuals or all females. If first reproduction typically occurs by 12 months, use 0, not 1; if it occurs between 12 and 24 months, use 1, etc.

3. age of first reproduction + \(z\) * (length of the reproductive period), where \(z\) is usually <0.5, depending on survivorship and the relative fecundity of young vs. old individuals in the population. For age of first reproduction, see (2) above. This approximation is useful when ages of first and last reproduction are the only available data, but finding the correct value of \(z\) may be tricky. In general, for a given length of reproductive period, \(z\) is lower for higher mortality during reproductive years and it is higher for relative fecundity skewed towards older age classes. To see how generation length is affected by deviation from these assumptions, you can use the spreadsheet mentioned above. Note that the length of the reproductive period depends on longevity in the wild, which is not a well-defined demographic parameter because its estimate often depends very sensitively on sample size.

4. generation length (as well as age of first reproduction for (2) and (3) above) should be calculated over all reproducing individuals. If the estimate of generation length differs between males and females it should be calculated as a weighted average, with the weighting equal to the number of reproducing individuals of the two sexes. However, if the two sexes are impacted differentially by some threat, this should be taken into account and pre-disturbance generation length should be used for both sexes before calculating the weighted average (see below for further discussion on pre-disturbance generation length).

5. for partially clonal taxa, generation length should be averaged over asexually and sexually reproducing individuals in the population, weighted according to their relative frequency.
6. for plants with seed banks, use juvenile period + either the half-life of seeds in the seed bank or the median time to germination, whichever is known more precisely. Seed bank half-lives commonly range between <1 and 10 years. If using the spreadsheet for such species, enter seed bank as one or several separate age classes, depending on the mean residence time in the seed bank.

The correct use of the methods described above requires that "age" is defined in a specific way. The definition affects, for instance, the age of first reproduction for equations in (2) and (3) above, as well as fecundity (F) as a function of age for the equation in (1) and in the spreadsheet. For purposes of these methods, an individual is zero-years old until its first birthday. For species with a distinct reproductive season (e.g., many species in temperate regions), F(0) is the number of offspring produced per individual in the reproductive season that is after the one in which the individual was born, regardless of how age is reckoned. In general (including other types of life histories, such as species with no specific, or a much longer, "reproductive season"), F(0) is the number of offspring produced per individual in its first 12 months. If an alternate definition is used, the formulae need to be modified to reflect the definition. For example, if age is defined such that age of first reproduction is 1 (not zero) when the first reproduction occurs by 12 months, then the formula in (2) should be "1/adult mortality + age of first reproduction – 1".

Options 2 and 3 are still appropriate if the interbirth interval is more than one year; a more precise calculation can be made in this case by using the spreadsheet (see above), and for each age class averaging fecundity over all individuals (or females) in that age class (regardless of whether they actually reproduced at that age). The turnover rate mentioned in the definition is not directly related to the interbirth interval; it reflects the average time it takes one group of breeding individuals to be replaced by its progeny.

It is not necessary to calculate an average or typical generation length if some subpopulations of the taxon differ in terms of generation length. Instead, use each subpopulation's generation length to calculate the reduction over the appropriate number of generations, and then calculate the overall population reduction (for criterion A) or overall estimated continuing decline (for criterion C1) using a weighted average of the reductions calculated for each subpopulation, where the weight is the size of the subpopulation 3 generations ago.

2.1.5 Types of evidence for reduction
Both Clause 4.2 of the BC Regulation 2017 and criterion A of IUCN (2001) refer to different types of direct and indirect evidence for reductions in population size. To qualify for listing, reductions of the above magnitude must be observed, estimated, projected, inferred or suspected (Clause 4.16). IUCN (2017) provides explicit definitions for these terms (Box 2).
Box 2. Types of evidence (after IUCN (2017) Section 5.1)

**Observed:** information that is directly based on well-documented observations of all known individuals in the population.

**Estimated:** information that is based on calculations that may include statistical assumptions about sampling, or biological assumptions about the relationship between an observed variable (e.g. an index of abundance) to the variable of interest (e.g. number of mature individuals). These assumptions should be stated and justified in the documentation. Estimation may also involve interpolation in time to calculate the variable of interest for a particular time step (e.g. a 10-year reduction based on observations or estimations of population size 5 and 15 years ago). For examples, see discussion under criterion A (section 5.1 of IUCN 2017).

**Projected:** same as “estimated”, but the variable of interest is extrapolated in time towards the future. Projected variables require a discussion of the method of extrapolation (e.g. justification of the statistical assumptions or the population model used) as well as the extrapolation of current or potential threats into the future, including their rates of change.

**Inferred:** information that is based on indirect evidence, on variables that are indirectly related to the variable of interest, but in the same general type of units (e.g. number of individuals or area or number of subpopulations). Examples include population reduction (A1d) inferred from a change in catch statistics, continuing decline in number of mature individuals (C2) inferred from trade estimates, or continuing decline in area of occupancy (B1b(ii,iii), B2b(ii,iii)) inferred from rate of habitat loss. Inferred values rely on more assumptions than estimated values. For example, inferring reduction from catch statistics not only requires statistical assumptions (e.g. random sampling) and biological assumptions (about the relationship of the harvested section of the population to the total population), but also assumptions about trends in effort, efficiency, and spatial and temporal distribution of the harvest in relation to the population. Inference may also involve extrapolating an observed or estimated quantity from known subpopulations to calculate the same quantity for other subpopulations. Whether there are enough data to make such an inference will depend on how large the known subpopulations are as a proportion of the whole population, and the applicability of the threats and trends observed in the known subpopulations to the rest of the taxon. The method of extrapolating to unknown subpopulations depends on the criteria and on the type of data available for the known subpopulations. Further guidelines are given under specific criteria (e.g. see section 5.1 (IUCN 2017) for extrapolating population reduction for criterion A assessments).

**Suspected:** information that is based on circumstantial evidence, or on variables in different types of units, for example, % population reduction based on decline in habitat quality (A1c) or on incidence of a disease (A1e). For example, evidence of qualitative habitat loss can be used to infer that there is a qualitative (continuing) decline, whereas evidence of the amount of habitat loss can be used to suspect a population reduction at a particular rate. In general, a suspected population reduction can be based on any factor related to population abundance or distribution, including the effects of (or dependence on) other taxa, so long as the relevance of these factors can be reasonably supported.
2.1.6 Inferring changes in population size from changes in geographic distribution

A reduction in population size may be based on a decline in geographic distribution (Clause 4.2 in conjunction with Subclause 4.2(2c)). The assumptions made about the relationship between habitat loss and population reduction have an important effect on the outcome of an assessment. In particular, the simplest assumption, that the relationship is linear, is not often true and may lead to over- or under-listing. IUCN (2017) gives the following examples to illustrate this. The population of a bird species may not be reduced by 50% if 50% of its habitat is lost (perhaps because it will colonise new habitats). Or, reduction may happen mostly in lower-density areas, leading to a faster decline in range than in population size. Conversely, if reductions occur predominantly in high-density areas, population reduction will be faster than can be deduced from range contraction (decrease in EOO) (Rodríguez 2002). Similarly, the population of a hollow-dependent mammal may be reduced by more than 50% if 50% of its habitat is lost due to logging in productive breeding sites that removes many suitable tree hollows.

In all cases, an understanding of the taxon and its relationship to its habitat, and the threats facing the habitat is central to sensible use of inference and projection in making the most appropriate assumptions about habitat loss and subsequent population reduction. These assumptions should be justified and documented.

IUCN (2017) notes that available population data may sometimes contradict habitat data (e.g. habitat seems to be declining in quality, but population numbers are stable). This can occur because: (1) one set of data is uncertain, biased, or dated, or (2) the population has a lagged response to loss of habitat (likely if generation time is long). In the first case, the assessors must use their judgement to decide which data are more certain. The implications of a possible lagged response in abundance to loss of habitat should, however, be considered when evaluating whether the species “is likely to undergo” a reduction of particular magnitude over the relevant future time frame. For example, if population reduction in the last 3 generations is 30% based on abundance data, which are adequate to determine trends, then the species should be listed as VU, even if habitat loss in the same period was 60%. However, if a lagged response in abundance to loss of habitat (i.e. the impact of habitat loss at present leads to a future reduction in the number of mature individuals) is likely, then the population may be expected to decline further in the future (even if habitat loss has stopped). In this case, listing as EN should be considered if the 60% loss of habitat is inferred to lead to a 60% reduction in the population within the next 3 generations.

2.1.7 Calculating reductions in population size

IUCN (2017) sections 4.5 and 5 provide extensive advice on the interpretation and calculation of reductions in population size. This advice provides recommendations on methods to calculate population reductions using statistical techniques and includes worked examples and advice on appropriate model selection (linear, exponential, accelerating or complex patterns of decline), population models and methods to deal with multiple subpopulations.
For taxa with more than one population or area of occurrence, reductions should be averaged across all populations and areas or across a sample of all populations and areas. Across the entire range of a species, some populations may be increasing, some may be declining and others may be stable. In such situations, the change should be weighted by the size of the population; for example, declines in large populations will outweigh increases in small populations. Box 3 shows an example calculation.

**Box 3. Protocol for estimating population reduction (after IUCN (2017) section 4.5.3)**

For species with multiple populations or occurrences, it is recommended that the available data on past reduction be presented in a table that lists all known populations, occurrences or parts of the range, and gives at least two of the following three values for each subpopulation:

1. the estimated abundance at a point in time close to the required base line for estimating population reduction (e.g. 3 generations ago), and the year of this estimate;
2. the most recent estimated abundance and its year;
3. suspected or inferred reduction (in %) over the last 3 generations.

If there are estimates of abundance for years other than those reported in (1) or (2), these should also be reported in separate columns of the same table. Any qualitative information about past trends for each population should be summarised in a separate column, as well as quantities calculated based on the presented data (see examples in IUCN 2017, section 4.5.3).

There are three important requirements:

a) The values should be based on estimates or indices of the number of mature individuals. If the values are based on indices, a note should be included that explains how the index values are expected to relate to the number of mature individuals, and what assumptions are necessary for this relationship to hold.

b) The populations or occurrences should be non-overlapping. This does not mean that there is no or infrequent dispersal among populations. The point of this requirement is to avoid double-counting as much as possible. ‘Occurrences’ are any type of non-overlapping subunits of the species, such as parts of the species’ range

c) Together, the populations or occurrences should include all those of the species within Australia (national assessment) or NSW (NSW State assessment). If this is not possible, a “population” named *Remainder* should include an estimate of the total number of mature individuals not included in the listed populations. This estimate, like others, can be uncertain (see below).

In many cases, there will be uncertainty, because the abundances are not known precisely, are in different units for different populations, or are available only from one or few populations. These cases are discussed below in a section on Dealing with uncertainty.

IUCN (2017) gives several examples of calculating population reductions under different scenarios of available data. One example for a species with three occurrences (Pacific, Atlantic & Indian) and a generation length of 20 years is reproduced below. The assessment date was 2001 (i.e. for these examples, the “present” is 2001 and "three generations ago" is 1941).
In this case, the “past” and “present” population estimates are not from the same year for all populations. Thus, it is necessary to make projections in order to estimate reduction for each population in the same time period. There are several types of projection. For example, it is necessary to project the population from the “past” census (in the 1930s) to 1941 (3 generations ago) as well as from the most recent census (in 1995) to the present.

Any information about past trends can be valuable in making such projections (as in the “Notes” in the example). For instance, given that most of the decline in the Pacific subpopulation has occurred in recent years, the estimate in the 1930s can be assumed to also represent the population in 1941 (3 generations ago). However, in this case, it is necessary to make a projection from the most recent estimate (in 1995) to 2001. If the estimated decline from 10000 to 7000 occurred in 20 years, then assuming a constant rate of decline during this period, annual rate of decline can be calculated as $1.77\% \left[ 1 - (7000/10000)^{1/20} \right]$, giving a projected decline of about 10.1\% in the 6 years from the last census (in 1995) to 2001, and a projected 2001 population of 6290 ($=7000\times(7000/10000)^{6/20}$). This means a 3-generation decline of 37\% (10000 to 6290).

When there is no evidence that the rate of decline is changing, exponential decline can be assumed. For example, for the “Indian Ocean” subpopulation, the 20-year reduction from 1961 to 1981 is 60\% per generation; corresponding to 4.48\% per year $[-0.0448=-(4000/10000)^{1/20}-1]$. Thus, the 3-generation decline can be estimated as 93.6\% $[-0.936=-(4000/10000)^{60/20}-1]$. Another way to calculate the 3-generation decline is based on an annual rate of change, which is 0.9552 (1-4.48\%). Thus, a 60-year population change is 0.9552$^{60}=0.064$; i.e. only 6.4\% of the population will remain after 60 years, which is a 93.6\% decline. The population size 3 generations ago can thus be estimated as 25000 $[=10000/(1-0.6)]$, and the current population as 1600 $[=4000\times(4000/10000)]$.

It is important to note that the assumption of the pattern of decline can make an important difference to the estimated reduction, and that exponential decline is not the only possible assumption. See the discussion in section 5 (Dealing with uncertainty).

The “Atlantic” subpopulation has been stable, so a reduction of 0\% is assumed. Combining the three estimates, the weighted average of reduction for the taxon is estimated as 63\% $[=(-0.37\times10+0\times8-0.936\times25)/43]$.

When such projections are used in estimating the overall reduction, the projected declines and projected subpopulation sizes should be given in different columns of the table than those that are used for the data (see completed table below).
As illustrated in Box 3, available data on population reductions may not correspond to the “time frame appropriate to the life cycle and habitat characteristics of the taxon” over which reductions must be assessed against the listing criteria. Interpolation or extrapolation may be required where the data are available for a longer or shorter period than the required time frame for assessing population reductions. In both cases, the best approach is to fit a regression model to the available data and use the appropriate time interval (e.g. between the present year and three generations lengths prior) on the fitted line to calculate the reduction. Fitting a model in this way helps to eliminate some of the variability in the data that may be attributable to natural fluctuations, and which should not be included when estimating population reductions (IUCN 2017).

Interpolation or extrapolation will require assumptions about the data and the trend that should be justified with reference to the life history and/or habitat characteristics of the taxon, and the processes driving its decline (e.g. pattern of exploitation, habitat loss, disease spread, disturbance events, etc.). For example, depending on the shape of the data, a linear or exponential regression model may be fitted. Assumptions about the rate of decline remaining constant, increasing or decreasing relative to the observed interval must be justified, especially where population reduction is estimated over long generation times from data over shorter time frames.

### Clause 4.3 – restricted geographic distribution and other conditions

Clause 4.3 is based on IUCN (2001) criterion B. The basis for Clause 4.3 is the level of exposure of a species to spatially correlated threatening processes (Mace & Lande 1991, Keith 1998, Mace et al. 2008, IUCN 2017). The larger a species’ distribution, the more its risk of exposure to threats will be spread across different locations. Conversely, species that have restricted geographic distributions, will have fewer opportunities for persistence because it is more likely that a single threatening process or event will adversely affect the entire species. Clause 4.3 is indirectly related to the small population paradigm (Caughley 1994), as certain measures of geographic distribution may be proxies for population size (Gaston 1992, Keith 1998). To be eligible for listing under Clause 4.3, a species must have a sufficiently restricted distribution AND meet at least two conditions specified in Subclauses 4.3d, 4.3e, and 4.3f. These additional conditions are discussed under section 2.4. This section discusses the interpretation and measurement of geographic distribution.

2.2.1 Geographic distribution

The geographic distribution of a species is defined in Clause 4.18(1) of the BC Regulation 2017 as ‘the area or areas in which a species [or ecological community] occurs, excluding cases of vagrancy.’ Geographic distribution may be assessed in a number of different ways, including the extent of occurrence, area of occupancy and area of suitable habitat.

2.2.2 Measures of geographic distribution

Under Clause 4.3, the geographic distribution of a species may be assessed by estimating the extent of occurrence, the area of occupancy or the area of suitable habitat. Each of these terms is defined in Clause 4.18(2).

(a) Extent of occurrence (EOO) is defined in Clause 4.18(2a) as the area of the total geographic range that includes all extant populations of the species. Its application in Clause 4.3 follows criterion B1 in IUCN (2001). Extent of occurrence can often be measured by a minimum convex polygon or convex hull (the smallest polygon in which no internal angle exceeds 180 degrees and which contains all the sites of occurrence). IUCN (2001) states that EOO may exclude discontinuities or disjunctions within the overall distributions of taxa (e.g. large areas of obviously unsuitable habitat). However, the consequences of excluding discontinuities vary, depending on whether the estimate of EOO is to be used for assessing the total distribution in Clause 4.3, or whether it is to be used for estimating or inferring reductions (Clause 4.2) or continuing declines (Subclauses 4.3e and 4.4d in conjunction with Subclause 4.2.2c). Box 4 summarises guidance from IUCN (2017) on how to estimate EOO under these different criteria.

Box 4. Estimating Extent of Occurrence

The following considerations apply to EOO as a measure of geographic distribution size in Clauses 4.3 and 4.10 of the BC Regulation 2017.

In relation to criterion B IUCN (2017) states that “exclusion of areas forming discontinuities or disjunctions from estimates of EOO is discouraged except in extreme circumstances because disjunctions and outlying occurrences accurately reflect the extent to which a large range size reduces the chance that the entire population of the taxon will be affected by a single threatening process. The risks are spread by the existence of outlying or disjunct occurrences irrespective of whether the EOO encompasses significant areas of unsuitable habitat (IUCN 2017). Inappropriate exclusions of discontinuities or disjunctions within the overall distribution of a taxon will underestimate EOO and consequently will underestimate the degree to which risk is spread spatially for the taxon” (IUCN 2017).

The following considerations apply to changes in EOO as a measure of reduction of population size in Clause 4.2, reduction of geographic distribution in Clause 4.9, and as an indicator of continuing decline in geographic distribution size in Subclauses 4.3e and 4.4d in conjunction with Subclause 4.2(2c) of the BC Regulation 2017.

Effects of outlying occurrences on estimates of EOO based on minimum convex polygons (also known as convex hulls) and their sensitivity to sampling effort makes them less suitable as a method for comparing two or more temporal estimates of EOO for assessing reductions or continuing declines. If outliers are detected at one time and
not another, this could result in erroneous inferences about reductions or increases. Therefore, a method such as the $\alpha$-hull (a generalisation of a convex hull) is recommended for assessing reductions of continuing declines in EOO because it substantially reduces the biases that may result from the spatial arrangement of habitat (Burgman & Fox 2003). The $\alpha$-hull provides a more repeatable description of the external shape of a species’ range by breaking it into several discrete patches when it spans uninhabited regions. Simulations show that the estimate of area and trend in area converges on the correct value as sample size increases unless other errors are large. Kernel estimators may be used for the same purpose but their application is more complex. IUCN (2017) and Burgman & Fox (2003) provide guidance on the calculation of $\alpha$-hulls.

In the case of migratory species, EOO should be based on the minimum of the breeding or non-breeding (wintering) areas, but not both, because such species are dependent on both areas, and the bulk of the population is found in only one of these areas at any time.

To ensure consistency with the definition of Area of Occupancy (AOO), if EOO is less than AOO, EOO should be changed to make it equal to AOO.

(b) **Area of occupancy** (AOO) is defined in Clause 4.18(2b) as the area within the total range (and hence within EOO) that is currently occupied by the species. It excludes unsuitable and unoccupied habitat. Its application in Clause 4.3 follows criterion B2 in IUCN (2001). In some cases, (e.g. irreplaceable colonial nesting sites, crucial feeding sites for migratory taxa) the area of occupancy is the smallest area essential at any stage to the survival of existing populations of a taxon (IUCN 2001). IUCN (2017) explains the rationale underpinning AOO as follows: “Suppose two species have the same EOO, but different values for AOO, perhaps because one has more specialised habitat requirements. For example, two species may be distributed across the same desert (hence EOO is the same), but one is wide ranging throughout (large AOO) while the other is restricted to oases (small AOO). The species with the smaller AOO may have a higher risk of extinction because threats to its restricted habitat (e.g. degradation of oases) are likely to reduce its habitat more rapidly to an area that cannot support a viable population. The species with the smaller AOO is also likely to have a smaller population size than the one with a larger AOO, and hence is likely to have higher extinction risks for that reason” (IUCN 2017). Estimates of AOO are highly sensitive to scale of measurement. The recommended scale to use is 2 x 2 km grid cells (IUCN 2017). This is necessary to ensure the scale used is matched to the IUCN criterion B2 and D2 thresholds. IUCN (2017) note that “use of the smallest available scale (finest grain) to estimate AOO (sometimes erroneously called ‘actual’ area’ or ‘actual AOO’ is not permitted, even though mapping a species’ distribution at the finest scale may be desirable for purposes other than calculating AOO”. The method of estimation of AOO is discussed in Box 5.

**Box 5. Estimating Area of Occupancy (after IUCN 2017 sections 4.10.1 – 4.10.3)**

Both IUCN (2001) and BC Regulation 2017 (Clause 4.18(3)) acknowledge that AOO should be estimated at a scale appropriate to the biology of the species, nature of threats and available data. IUCN (2017) recommends that this be done by using a standard
scale based on 2 x 2 km grid cells, as this is commensurate with the values of the thresholds in IUCN criterion B2.

Problems of scale

Classifications based on the area of occupancy (AOO) may be complicated by problems of spatial scale. Estimating the quantity of occupied habitat for taxa with markedly different body sizes, mobility and home ranges intuitively requires different spatial scales of measurement. Nevertheless, many of the major threats that impact those same taxa operate at common landscape and seascape scales. For this reason, the Red List criteria specify fixed range size thresholds to identify taxa at different levels of extinction risk.

The need to scale estimates of AOO consistently follows logically from the adoption of fixed AOO thresholds in the Red List criteria and the sensitivity of AOO estimates to measurement scale. “The finer the scale at which the distributions or habitats of taxa are mapped, the smaller the area will be that they are found to occupy, and the less likely it will be that range estimates … exceed the thresholds specified in the criteria. Mapping at finer spatial scales reveals more areas in which the taxon is unrecorded. Conversely, coarse-scale mapping reveals fewer unoccupied areas, resulting in range estimates that are more likely to exceed the thresholds for the threatened categories. The choice of scale at which AOO is estimated may thus, itself, influence the outcome of Red List assessments and could be a source of inconsistency and bias.” (IUCN 2001).

These effects are illustrated in the graph below (from Keith 2009 and Nicholson et al. 2009), which shows how the scale at which AOO is measured may influence whether or not different species meet the AOO thresholds for different categories of threat. The broken vertical line shows the standard scale recommended for assessment of AOO by IUCN (2017). At this scale, three of the species are within the AOO threshold for Endangered and one is outside the AOO thresholds for all three categories of threat.

To reduce scale-related bias, some estimates of AOO may require standardisation to an appropriate reference scale. Below, a simple method of estimating AOO is described, an appropriate reference scale is recommended, and a method of standardisation is described for cases where the available data are not at the reference scale.

Methods for estimating AOO
There are several ways of estimating AOO, but for the purpose of these guidelines we assume estimates have been obtained by counting the number of occupied cells in a uniform grid that covers the entire range of a species (see Figure 2.2.2), and then tallying the total area of all occupied cells:

$$\text{AOO} = \text{no. occupied cells} \times \text{area of an individual cell}$$

The ‘scale’ of AOO estimates can then be represented by the area of an individual cell in the grid (or alternatively the length of a cell). There are other ways of representing AOO, for example, by mapping and calculating the area of polygons that contain all occupied habitat. The scale of such estimates may be represented by the area of the smallest mapped polygon (or the length of the shortest polygon segment), but these alternatives are not recommended. If different grid locations or origins (reference points of the grid) result in different AOO estimates, the minimum estimate should be used.
Figure 2.2.2. Two examples of the distinction between extent of occurrence and area of occupancy.

(A) is the spatial distribution of known, inferred or projected sites of present occurrence.

(B) shows one possible boundary to the extent of occurrence, which is the measured area within this boundary.

(C) shows one measure of area of occupancy which can be achieved by the sum of the occupied grid squares.

(taken from IUCN (2001))

The appropriate scale

“In all cases, 4 km$^2$ ($2 \times 2$ km) cells are recommended as the reference scale for estimating AOO to assess criteria B2 and D2. If an estimate was made at a different scale, especially if data at different scales were used in assessing species in the same taxonomic group, this may result in inconsistencies and bias.” (IUCN 2017). Scales of 3.2 km grid size or coarser (larger) are inappropriate because they do not allow any taxa to be listed as Critically Endangered (CR); even species that occur within a single grid will have an area that exceeds 10 km$^2$, the AOO threshold for Critically Endangered under criterion B of IUCN (2001). Scales of 1 km grid size or smaller tend to list more taxa at higher threat categories than these categories imply. For most cases, a scale of 4 km$^2$ cells as the reference scale is recommended by (IUCN 2017). In any case, the scale for AOO should not be based on EOO (or other measures of range area), because AOO and EOO measure different factors affecting extinction risk.

(c) Area of suitable habitat is defined in Clause 4.18(2c) as ‘the area within the total range that includes occupied and unoccupied suitable habitat, but excludes unsuitable habitat.’ Maps of suitable habitat may be derived from interpretation of
remote imagery and/or analyses of spatial environmental data using simple combinations of GIS data layers, or by more formal statistical habitat models (e.g. generalised linear and additive models, decision trees, Bayesian models, regression trees, etc.). Habitat maps can provide a basis for estimating AOO and EOO and, if maps are available for different points in time, rates of change can be estimated (IUCN 2017). They cannot be used directly to estimate a taxon’s AOO because they often map an area that is larger than the occupied habitat (i.e. they also map areas of suitable habitat that may presently be unoccupied). However, they may be a useful means of estimating AOO indirectly, for which IUCN stipulates three conditions that must be met.

i) Maps must be justified as accurate representations of the habitat requirements of the species and validated by a means that is independent of the data used to construct them.

ii) The mapped area of suitable habitat must be interpreted to produce an estimate of the area of occupied habitat.

iii) The estimated area of occupied habitat derived from the map must be scaled to the grid size (2 x 2 km) that is appropriate for IUCN criterion B2 (AOO) thresholds.

Habitat maps can vary widely in quality and accuracy (condition i). A map may not be an accurate representation of habitat if key variables are omitted from the underlying model. For example, a map would over-estimate the habitat of a forest-dependent montane species if it identified all forest areas as suitable habitat, irrespective of altitude. The spatial resolution of habitat resources also affects how well maps can represent suitable habitat. For example, specialised nest sites for birds, such as a particular configuration of undergrowth or trees with hollows of a particular size, do not lend themselves to mapping at coarse scales. Application of habitat maps to the assessment of species for listing under the BC Act, should therefore be subject to an appraisal of mapping limitations, which should lead to an understanding of whether the maps over-estimate or under-estimate the area of suitable habitat.

Habitat maps may accurately reflect the distribution of suitable habitat, but only a fraction of suitable habitat may be occupied (condition ii). Therefore, the area of suitable habitat may be an upper bound of the possible AOO although, depending on the proportion of suitable habitat actually occupied, it could be substantially larger than any plausible upper bound of AOO. Low habitat occupancy may result because other factors are limiting – such as availability of prey, impacts of predators, competitors or disturbance, dispersal limitations, etc. In such cases, the area of mapped habitat could be substantially larger than AOO and will therefore need to be adjusted (using an estimate of the proportion of habitat occupied) to produce a valid estimate of AOO. This may be done by random sampling of suitable habitat grid cells, which would require multiple iterations to obtain a stable mean value of AOO (IUCN 2017).

Habitat maps are produced at a resolution determined by the input data layers (satellite images, digital elevation models, climate surfaces, etc.). Often these will be at finer scales than those required to estimate AOO (condition iii), and consequently scaling up will be required (see IUCN 2017).

In those cases where AOO is less than the area of suitable habitat, the population may be declining within the habitat, but the habitat may show no indication of
change (Rodriguez 2002; IUCN 2017). Hence estimates of population reduction (under Clause 4.2) could be both inaccurate and non-precautionary.

However, if a decline in mapped habitat area is observed (and the map is a reasonable representation of suitable habitat – condition i), then the population is likely to be declining at least at that rate. This is a robust generalisation because even the loss of unoccupied habitat can reduce population viability (Levins 1970; Hanski & Gilpin 1997; Beissinger & McCulloch 2002). Thus, if estimates of AOO are not available, then the observed decline in mapped habitat area can be used to invoke "continuing decline" in Subclauses 4.3e and 4.4d, and the rate of such decline can be used as a basis for calculating a lower bound for population reduction under Clause 4.2.

### 2.2.3 Size of geographic distribution

To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, a species must have a geographic distribution that is estimated or inferred* to be very highly restricted (Subclause 4.3a), highly restricted (Subclause 4.3b) or moderately restricted (Subclause 4.3c), in addition to meeting other particular conditions (Subclauses 4.3d, 4.3e or 4.3f). The corresponding listing criteria in IUCN (2001) provide indicative guidance for quantitative interpretation of these terms. (Table 2).

### 2.3 Clauses 4.4 & 4.5 – number of mature individuals

Clauses 4.4 and 4.5 are based on IUCN (2001) criteria C and D. The basis for Clauses 4.4 and 4.5 is the small population paradigm (Caughley 1994): a small population is more likely to become extinct than a large one (see also Mace & Lande 1991, Keith 1998, Mace et al. 2008, IUCN 2017). For the purposes of assessing Clauses 4.4 and 4.5, the sizes of species’ populations are assessed by estimating or inferring the number of mature individuals.

#### 2.3.1 Mature individuals

Clause 4.17(1) (after IUCN 2001) defines mature individuals as ‘individuals in the

* See Box 2 for definitions of ‘estimated’ and ‘inferred’
wild known, estimated or inferred to be capable of producing viable offspring’. The total number of mature individuals excludes individuals that are too young (juvenile), too old (senescent), too moribund (for example, diseased) or otherwise unable to produce viable offspring (for example, due to low population density). Supressed individuals (e.g., individuals that will quickly become reproductive if another mature animal dies) should be included in the estimate of mature individuals (IUCN 2017).

Clause 4.17(2) to 4.17(7) (after IUCN 2001) provides guidance on the interpretation of mature individuals in the following special cases:

(a) In populations with biased sex ratios, it is appropriate to use a lower value for the total number of mature individuals in a way that takes this into account.

(b) In populations that fluctuate (see Section 2.4.2.4), the number of mature individuals will refer to a minimum number of individuals that are present most of the time (in a time span appropriate to the life cycle and habitat characteristics of the species), and will thus usually be much less than the mean number present.

(c) In clonal organisms, reproducing units may be regarded as mature individuals, so long as they survive independently of one another. However, if clonally reproduced individuals are more limited in viability or dispersal ability than sexually reproduced individuals, the total number of mature individuals may be reduced accordingly to take this into account.

(d) For species in which individuals have synchronous dormant life stages, the number of mature individuals should be assessed during, or projected for, a time when mature individuals are available for breeding.

(e) Re-introduced individuals must have produced viable offspring (after the individuals were re-introduced) before they are counted as mature individuals.

(f) Captive, cultivated, or artificially maintained individuals cannot be counted as mature individuals.

2.3.2 **Number of mature individuals**

To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, under Clause 4.4, the estimated* total number of mature individuals of a species must be **very low** (Subclause 4.4a), **low** (Subclause 4.4b) or **moderately low** (Subclause 4.4c) in addition to meeting other particular conditions (either subclause 4.4d OR 4.4e). To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, under Clause 4.5, the estimated* total number of mature individuals of a species must be **extremely low** (Subclause 4.5a), **very low** (Subclause 4.5b) or **low** (Subclause 4.5c) and no additional conditions are required. The corresponding listing criteria in IUCN (2001) provide indicative guidance for quantitative interpretation of these terms (Table 3).

2.4 **Subclauses 4.3d,e,f & 4.4d,e – continuing decline, fragmentation, concentration and fluctuation**

To be eligible for listing under Clause 4.3, a species must have a geographic distribution that is estimated or inferred to be restricted to particular degrees (Subclauses 4.3a-c). Similarly, eligibility for listing under Clause 4.4, requires a very low, low or moderately low number of mature individuals. For Clause 4.3, a species must meet at least two of three further conditions: Subclauses 4.3d, 4.3e, 4.3f. For Clause 4.4, one of two further requirements must be met: Subclauses 4.4d or 4.4e. Subclauses 4.3e and 4.4d-e refer to a projected or continuing decline in specified species parameters (section 2.4.1). Subclauses 4.3d and 4.3f, and components of 4.4e refer to a combination of conditions including severe fragmentation, the number of populations or locations of the species, and extreme fluctuations (section 2.4.2).

2.4.1 **Continuing decline**

To meet Subclause 4.3e, a projected or continuing decline must be observed, estimated, projected or inferred* in any of:

(i) an index of abundance appropriate to the taxon,
(ii) the geographic distribution of the species,
(iii) habitat area, extent or quality, or
(iv) the number of locations in which the species occurs or of populations of the species,

To meet Subclause 4.4e(i) there needs to be a **continuing decline** in the number of mature individuals (according to an index of abundance appropriate to the species).

---

* See Box 2 for definitions of ‘observed’, ‘estimated’ and ‘inferred’
"A continuing decline is a recent, current or projected future decline (which may be smooth, irregular or sporadic) which is liable to continue unless remedial measures are taken. Fluctuations (see section 2.4.2.4) will not normally count as continuing declines, but an observed decline should not be considered as a fluctuation unless there is evidence for this." (IUCN 2001)

Note that a continuing decline is not possible without a ‘reduction’ (which must be assessed under Clause 4.2), but a reduction is possible without a continuing decline: if a reduction has ‘ceased’ (Clause 4.2), there cannot be a continuing decline. However, continuing declines need not be continuous; they can be sporadic, occurring at unpredictable intervals, but they must be likely to continue into the future. Relatively rare events can be considered to contribute to a continuing decline if they happened at least once within the last three generations or 10 years (whichever is longer), and it is likely that they may happen again in the next three generations or 10 years (whichever is longer), and the population is not expected to recover between the events.

Continuing declines at any rate can be used to qualify taxa under Clause 4.3 or 4.4. This is because taxa under consideration under these clauses are already characterized by restricted ranges or small population size (IUCN 2017).

Rates of continuing decline over long generation times (in the same way as reductions) may be estimated from data over shorter time frames (IUCN 2017). When extrapolating data from shorter time frames, assumptions about the rate of decline remaining constant, increasing or decreasing, relative to the observed interval must be justified with reference to threatening processes, life history or other relevant factors.

If habitat is declining (in area, extent or quality) but abundance is not, this may be because (i) there is a delay in the population's response to lower carrying capacity, perhaps because the population is below the carrying capacity for other reasons (such as harvest), (ii) habitat is declining in areas not currently occupied by the taxon, or (iii) habitat is not correctly identified. In the case of (i), the population will eventually be impacted; in the case of (ii) the loss of recolonization options may eventually impact the population. In both cases, Clause 4.3e may be invoked even if the population is not undergoing a continuing decline (IUCN 2017).

To meet Subclause 4.4d a continuing decline in the number of mature individuals is required (according to an index of abundance appropriate to the species). To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, under Clause 4.4d, an observed, estimated or projected continuing decline must be very large (Critically Endangered), large (Endangered) or moderate (Vulnerable) up to a maximum of 100 years in the future. The corresponding listing criteria in IUCN (2001) provide indicative guidance for quantitative interpretation of these terms (Table 4).

2.4.2 Fragmentation, concentration and fluctuation

To be eligible for listing under Subclause 4.3d, the population or habitat of the species is severely fragmented or nearly all the mature individuals of the species occur within a small number of locations.

To be eligible for listing under Subclause 4.3f, extreme fluctuations occur in any of the following:
(i) an index of abundance appropriate to the taxon,
(ii) the geographic distribution of the species,
(iii) the number of locations in which the species occur or of populations of the species.

To be eligible for listing under Subclause 4.4eii at least one of the following applies:
(A) the number of individuals in each population of the species is
   (I) for critically endangered species—extremely low, or
   (II) for endangered species—very low, or
   (III) for vulnerable species—low,
(B) all or nearly all mature individuals of the species occur within one population,
(C) extreme fluctuations occur in an index of abundance appropriate to the species.

The definitions of terms and concepts associated with these conditions are discussed in the following sections.

2.4.2.1 Severe fragmentation

Clause 4.19 defines severe fragmentation as follows: “The population or habitat of a species is severely fragmented if individuals of the species are distributed among sub-populations or patches of habitat that are small and isolated relative to the life cycle and habitat characteristics of the species.” Species with severely fragmented populations or habitat are exposed to greater risks of extinction than other species because their small populations may go extinct, with a reduced probability of recolonisation (IUCN 2001). Furthermore, the reduced movement of individuals between populations or occupied habitat patches reduces the likelihood that declining populations will be rescued by migration from other patches (Levins 1969; Gonzalez et al. 1998).
Fragmentation must be assessed at a scale that is appropriate to biological isolation in the taxon under consideration. In general, taxa with highly mobile adult life stages or with a large production of small mobile diasporas are considered more widely dispersed, and hence not so vulnerable to isolation through fragmentation of their habitats. Taxa that produce only small numbers of diasporas (or none at all), or only large ones, are less efficient at long distance dispersal and therefore more easily isolated.

In certain circumstances severe fragmentation may be inferred from habitat information (IUCN 2001), for example, where there is evidence of trends indicating that habitat patches are becoming smaller, more numerous and more isolated from one another. If natural habitats have been fragmented (e.g. old growth stands within timber production forests, woodland remnants in agricultural landscapes, etc.), this can be used as direct evidence for fragmentation for taxa with poor dispersal ability.

In cases where data are available on (i) the spatial distribution of occupied habitat, (ii) some aspect of the dispersal ability of the taxon (e.g. average dispersal distance), and (iii) average population density in occupied habitat (e.g. information on territory size, home range size, etc.), IUCN (2017) proposes that species can be considered to be severely fragmented if most (>50%) of its total area of occupancy is in habitat patches that are (1) smaller than would be required to support a ‘viable’ population, and (2) separated from other habitat patches by a large distance relative to the dispersal capabilities of the species (IUCN 2017). Note that the existence (or even a large number) of small habitat patches, of itself, is insufficient evidence of severe fragmentation.

For (1), the area for a viable population should be based on rudimentary estimates of population density, and on the ecology of the taxon (IUCN 2017). For example, for many vertebrates, patches that can support fewer than a hundred individuals may be considered likely to be smaller than ‘viable’ size. For (2), the degree of isolation of patches should be based on dispersal distance of the taxon (IUCN 2017). For example, patches that are isolated by distances several times greater than the (long-term) average dispersal distance of the taxon may be considered isolated.

For many taxa, the information on population density and dispersal distance may be inferred from other similar taxa. Biologically informed values can be set by the assessors for large taxonomic groups (families or even orders), or for other groupings of taxa based on their biology. For example, in bryophytes information on the effects of isolation of subpopulations is often lacking. It is recommended that in most circumstances, a minimum distance greater than 50km between subpopulations of taxa without spore dispersal can indicate severe fragmentation, and a distance of between 100km and 1,000km for taxa with spores (Hallingbäck et al. 2000).

The definition of severe fragmentation is based on the distribution of populations. This is often confused with the concept of "location" (see section 2.4.2.3), but is independent of it. A taxon may be severely fragmented, yet all the isolated populations may be threatened by the same major factor (single location), or each population may be threatened by a different factor (many locations).
2.4.2.2 Number of populations

In the BC Regulation 2017, usage of the term ‘population’ (singular) follows IUCN (2001) where a ‘population’ is defined as the total number of individuals of a taxon. This applies in Clause 4.2 and 4.3d. This differs from common biological usage of the term (e.g. Begon et al. 2006). Instead, IUCN (2001) applies the term ‘subpopulations’ to the common biological meaning of ‘population’. The BC Regulation 2017 (listing criteria) also follows the common biological usage of ‘populations’ (usually plural, but not always) (equivalent to subpopulations of IUCN2001) in Clause 4.1(5), 4.3eiv, 4.3fiii, 4.4eiiA. Based on IUCN’s (2001) definition of subpopulations, populations are here defined as ‘geographically or otherwise distinct groups of individuals within the same species, between which there is little demographic or genetic exchange (typically one successful migrant individual or gamete per year or less).’ Although populations typically have little demographic or genetic exchange, this may or may not amount to their complete isolation.

Operational methods for determining the number of populations may vary from species to species. In tree species, for example, a population can be defined as a spatially distinct occurrence of the species that experiences insignificant seed or pollen migration from other populations within a generation.

Subclauses 4.4eiiA and 4.4eiiB are invoked for species where all or nearly all mature individuals are observed or inferred to occur within one population (4.4eiiB) or where the number of individuals in each population of the species is (4.4eiiA):

(I) for critically endangered species—extremely low, or

(II) for endangered species—very low, or

(III) for vulnerable species—low,

The corresponding listing criteria in IUCN (2001) provide indicative guidance for interpretation of thresholds for population size in each population (Table 5) and cases where ‘nearly all mature individuals’ occur within one population (Table 6).

</tbody>
</table>

2.4.2.3 Number of locations

Following IUCN (2001), “The term ‘location’ defines a geographically or ecologically distinct area in which a single threatening event can rapidly affect all individuals of the taxon present. The size of the location depends on the area covered by the threatening event and may include part of one or many populations. Where a taxon is affected by more than one threatening event, location should be defined by considering the most serious plausible threat.”

Justification for the number of locations used in assessments should consider all areas whether they are under threat or not (see below), and, for areas that are under threat, should include reference to the most serious plausible threat(s) (IUCN 2017). For example, where the most serious plausible threat is habitat loss, a location is an area where a single development project can eliminate or severely reduce the population. Where the most serious plausible threat is volcanic eruption, hurricane, tsunami, frequent flood or fire, locations may be defined by the previous or predicted extent of lava flows, storm paths, inundation, fire paths, etc. Where the most serious plausible threat is collection or harvest, then locations may be defined based on the size of jurisdictions (within which similar regulations apply) or on the level of access (e.g. ease with which collectors may reach different areas), as well as on the factors that determine how the levels of exploitation change (e.g. if collection intensity in two separate areas changes in response to the same market trends in demand, these may be counted as a single location).

If two or more populations occur within an area that may be threatened by one such event, they must be counted as a single location. Conversely, if a single population covers an area larger than may be affected by any single event, it must be counted as more than one location (IUCN 2017).

Where the most serious plausible threat does not affect all of the species’ distribution, other threats can be used to define and count locations in those areas not affected by the most serious plausible threat (IUCN 2017).
If there are two or more serious plausible threats, the number of locations should be based on the threat that results in the smallest number of locations (IUCN 2017).

When parts of the distribution are not affected by any threat, IUCN (2017) recommends the following options under different circumstances: (a) number of locations is not used in the assessment (i.e. the subcriteria that refer to the number of locations are consequently not met), especially if the unaffected area is more than half the species’ range; (b) number of locations in the unaffected areas is set to the number of populations in those areas, especially if there are several populations; (c) the number of locations is based on the smallest size of locations in the currently affected areas; (d) the number of locations is based on the most likely threat that may affect the currently-unaffected areas in the future. In any case, the basis of the number of locations should be documented.

In the absence of any plausible threat for the taxon, the "location" part of Subclause 4.3d cannot be invoked.

Subclause 4.3d is invoked for species in which nearly all mature individuals are observed or inferred to occur within a small number of locations. The corresponding listing criteria in IUCN (2001) provide indicative guidance for interpretation of cases where ‘nearly all mature individuals’ occur within a ‘small number of locations’ (Table 7).

</table>

2.4.2.4 Extreme fluctuations

Clause 4.20 of the BC Regulation 2017 states that “extreme fluctuations occur when the population or distribution of a species varies reversibly, widely and frequently, as:

(a) indicated by changes of:

(i) an index of abundance appropriate to the taxon, or
(ii) the geographic distribution of the species, or
(iii) the number of locations or populations of the species, or

(b) inferred from the life history or habitat biology of the species.
The cause of fluctuations must be understood or inferred so that they may be distinguished from declines or reductions.”

Extreme fluctuations are included in Subclauses 4.3f and 4.4eC in recognition of the positive relationship between extinction risk and variance in the rate of population growth (Burgman et al. 1993). Populations that undergo extreme fluctuations are likely to have highly variable growth rates, and are therefore likely to be exposed to higher extinction risks than populations with lower levels of variability. The effect of extreme fluctuations on the extinction risk will depend on both the degree of isolation and the degree of synchrony of the fluctuations between populations (IUCN 2017).

Population fluctuations may vary in magnitude and frequency (IUCN 2017, Figure 4.4). For the ‘extreme fluctuations’ subclauses to be invoked, populations would normally need to fluctuate by at least 10-fold (i.e. an order of magnitude difference between population minima and maxima). Fluctuations may occur over any time span, depending on their underlying causes (IUCN 2017). Short-term fluctuations that occur over seasonal or annual cycles will generally be easier to detect than those that occur over longer time spans, such as those driven by rare events or climatic cycles such as El Niño. Fluctuations may occur regularly or sporadically (i.e. with variable intervals between successive population minima or successive population maxima).

If there is regular or occasional dispersal (of even a small number of individuals, seeds, spores, etc) between all (or nearly all) of the populations, then the degree of fluctuations should be measured over the entire population (IUCN 2017). In this case, Subclauses 4.3f and 4.4eC would be met only when the overall degree of fluctuation (in the total population size) is larger than one order of magnitude. If the fluctuations of different populations are independent and asynchronous, they would cancel each other to some extent when fluctuations of the total population size are considered.

If, on the other hand, the populations are totally isolated, the degree of synchrony between the population is not as important (IUCN 2017) and it is sufficient that a majority of populations each show extreme fluctuation to meet Subclauses 4.3f and 4.4eC. In this case, if most of the populations show fluctuations of an order of magnitude, then the subclauses would be met (regardless of the degree of the fluctuations in total population size).

Between these two extremes, if dispersal is only between some of the populations, then the total population size over these connected populations should be considered when assessing fluctuations; each set of connected populations should be considered separately (IUCN 2017).

Population fluctuations may be difficult to distinguish from directional population changes, such as continuing declines, reductions or increases. Figure 4.1 shows examples where fluctuations occur independent of, and in combination with, directional changes. A reduction should not be interpreted as part of a fluctuation unless there is good evidence for this. Fluctuations must be inferred only where there is reasonable certainty that a population change will be followed by a change in the reverse direction within a generation or two. In contrast, directional changes will not necessarily be followed by a change in the reverse direction.
There are two main ways that extreme fluctuations may be diagnosed (IUCN 2017): (i) by interpreting population trajectories based on an index of abundance appropriate for the taxon; and (ii) by using life history characteristics or habitat biology of the taxon.

i) Population trajectories must show a recurring pattern of increases and decreases (see Figure 4.1 below). Normally, several successive increases and decreases would need to be observed to demonstrate the reversible nature of population changes, unless an interpretation of the data was supported by an understanding of the underlying cause of the fluctuation (see ii). Successive maxima or minima may be separated by intervals of relatively stable population size.

ii) Some organisms have life histories prone to boom/bust dynamics. Examples include fish that live in intermittent streams, granivorous small mammals of arid climates, and plants that respond to stand-replacing disturbances. In these cases, there is dependence on a particular resource that fluctuates in availability, or a response to a disturbance regime that involves predictable episodes of mortality and recruitment. An understanding of such relationships for any given taxon may be gained from studies of functionally similar taxa, and inference of extreme fluctuations need not require direct observation of successive increases and decreases.

In all cases, assessors must be reasonably certain that fluctuations in the number of mature individuals represent changes in the total population, rather than simply a flux of individuals between different life stages. For example, in some freshwater invertebrates of intermittent water bodies, the number of mature individuals increases after inundation which stimulates emergence from larval stages. Mature individuals reproduce while conditions remain suitable, but die out as the water body dries, leaving behind immature life stages (e.g. eggs) until the next inundation occurs. Similarly, fires may stimulate mass recruitment from large persistent seed banks when there were few mature individuals before the event. As in the previous example, mature plants may die out during the interval between fires, leaving a store of immature individuals (seeds) until they are stimulated to germinate by the next fire. Such cases do not fall within the definition of extreme fluctuations unless the dormant life stages are exhaustible by a single event or cannot persist without mature individuals. Plant taxa that were killed by fire and had an exhaustible canopy-stored seed bank (serotinous obligate seeders), for example, would therefore be prone to extreme fluctuations because the decline in the number of mature individuals represents a decline in the total number.
To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, under clause 4.6, the estimated* (see Box 2) probability of extinction must be extremely high (Subclause 4.6a), very high (Subclause 4.6b) or high (Subclause 4.6c). The corresponding listing criteria in IUCN (2001) provide indicative guidance for quantitative interpretation of these terms (Table 8). A guide to quantifying extinction probability can be found in IUCN (2017). A population viability analysis (PVA) is one of the more common techniques used to quantitatively assess extinction probability (IUCN, 2017) and IUCN (2017) stress that qualitative assessments of extinction probability cannot be accepted for criterion E. Which method is appropriate depends on the availability of data and the ecology of the taxon (IUCN 2017).

2.6 **Clause 4.7 – very highly restricted geographic distribution**

Under Clause 4.7, a species may be eligible for listing as Vulnerable if “the geographic distribution of the species or the number of locations of the species is very highly restricted such that the species is prone to the effects of human activities or stochastic events within a very short time period.”

Clause 4.7 is based on IUCN (2001) criterion D2 and the small population paradigm (Caughley 1994). The very highly restricted geographic distribution under Clause 4.7 is defined such that the population is prone to the effects of human activities or stochastic events within a very short time period in an uncertain future, and is thus capable of becoming Endangered, Critically Endangered or even Extinct in a very short time period (e.g., within one or two generations after the threatening event occurs, IUCN 2017). The numerical thresholds of area of occupancy (typically less than 20 km²) and number of locations (typically less than 5) given by (IUCN 2001) are indicative examples and are not intended to be interpreted as strict thresholds.

Unlike Clause 4.3, Clause 4.7 has no additional requirements relating to continuing decline, fragmentation, population concentration or fluctuation. However, the focus of Clause 4.7 is not only on the area threshold or threshold number of locations (for which many taxa could qualify), but the risk that the taxon could suddenly become highly threatened or extinct. So, simply meeting the indicative (or any other) threshold for AOO or number of locations is not sufficient, of itself, for a taxon to be eligible for listing under Clause 4.7. Unlikely events (e.g. eruption of an inactive volcano), non-specific events that were not observed in similar species (e.g. an unspecified disease epidemic), or events unlikely to cause extinction (e.g. because the species has survived many hurricanes, or is likely to adapt to global warming, etc.) would not qualify for listing under Clause 4.7. The threatening processes (stochastic events or human activities) that lead to this listing must be specified in the justification for listing.
3 Assessments of Populations

Under the BC Act 2016, Clause 1.6(1), a species includes:
(a) a defined subspecies, and
(b) a taxon below a subspecies, and
(c) a recognisable variant of a subspecies or taxon, and
(d) a population of a particular species (being a group of organisms, all of the same species, occupying a particular area).

The IUCN (2001) Red List criteria assign a different meaning to the term, ‘population’ which, in that system, refers to the total number of individuals of a taxon. IUCN (2001) defines ‘subpopulation’ as a geographically or otherwise distinct groups in the population between which there is little demographic or genetic exchange (typically one successful migrant individual or gamete per year or less). ‘Subpopulation’ as defined by IUCN (2001), is therefore the analogous term to ‘population’, as defined under the BC Act 2016.

Listings of Populations should clearly establish the ‘particular area’ of the population. This area may be large or small, but will usually be defined by some spatial discontinuity or other discriminating feature in the distribution of the species to help distinguish individuals that belong to the listed population from those of other populations. Many currently listed populations have been defined by the Local Government Area (LGA) in which they occur, but these LGAs may change over time, making such a listing problematic. Alternatively, other particular areas may be geographic areas, water catchments or suburbs (e.g. Woronora Plateau, Hunter Valley, Bateau Bay) defined by a cited source.

Nominations of populations for listing as Critically Endangered, Endangered or Vulnerable under the BC Act 2016 must meet Clause 4.1(5) of the BC Regulation 2017 (Special additional criteria for listing populations) and must be assessed under Clauses 4.2-4.7 of the BC Regulation 2017. A population is eligible for listing if it meets both of the subclauses of Clause 4.1(5a) and Clause 4.1(5b) AND any one of Clauses 4.2-4.7. Guidance for interpreting Clauses 4.2-4.7 may be obtained by references to the relevant sections on these Clauses for assessing species (Part 2 of these guidelines).

Consequently, listings of populations of species can be made under the BC Act utilising the criteria for species as described in Part 2 of these guidelines, provided the following additional criteria are met:
Clause 4.1 (5) of the BC regulation 2017) states that: A population of a species is not eligible to be listed as a threatened species under any of the criteria specified in the clauses 4.2-4.7 unless:
(a) the species to which the population belongs is not separately listed as a threatened species, and
(b) the population is, in the opinion of the Scientific Committee, of significant conservation value based on its role in the conservation of the species or of a number of other species.

These matters will be considered in detail below.
3.1 The species to which the population belongs is not separately listed as a threatened species

Only species that are not currently listed as a threatened species (i.e. as critically endangered, endangered, or vulnerable) in NSW under the BC Act are eligible for listing as populations on the BC Act.

3.2 The population is, in the opinion of the Scientific Committee, of significant conservation value based on its role in the conservation of the species or of a number of other species

The intent of Clause 4.1(5b) of the BC Regulation 2017 is to focus the listing of populations to those where it can be demonstrated that the population plays a significant role in the conservation of the species of which the population is a part, or the population plays a significant role in the conservation of a number of other species.

Several measures are indicative of the conservation value of a population. These include (but are not limited to):

1. populations that make significant contributions to the species via:
   a. genetic, morphological and ecological distinctiveness or are considered to provide such distinctiveness via occupation of novel, rare or distinctive environmental niches;
   b. relative population abundance or habitat area contributing to species viability;
   c. geographic placement such that functional connectivity is enabled between other substantial populations (i.e. ‘stepping stone’ populations without which significant fragmentation would occur);
   d. occupying likely relictual, refugial or source habitat, including areas where populations may retreat to and potentially subsequently expand from;
   e. providing adaptive capacity for the species under changing climates and/or threats. This may include aspects of disjunction and range margins, genetic diversity, areas of relatively high diversity of habitat or topographic heterogeneity;
   f. value for scientific research or education;
   g. a combination of the above.

2. populations that make a significant contribution to the conservation of other species, including:
   a. Key dispersal agents;
   b. Key pollinators;
   c. Key elements of habitat structure;
   d. ecological engineers that create or maintain habitat structure critical for other species;
   e. apex predators that create or maintain community structure critical for other species;
   f. species that play a significant role in stimulating or facilitating ecosystem functions like water infiltration, soil retention, etc; or
   g. other elements that are important to the survival of other species.
3.2.1 **Populations that make significant contributions to the species**

Populations may be significant for the species for a variety of reasons.

Populations may be genetically distinct if they include unique loci or alleles or unique distinctive combinations of alleles. Identification of such populations will usually require molecular analyses with sufficiently stratified sampling to draw comparative inferences about these properties.

Morphologically distinct populations comprise individuals that share morphological features that set them apart from other populations of the species. Identification of such populations may emerge from comparative morphometric studies, but may also be based on possession of unique character traits. *Zieria smithii* Jackson at Diggers Head and Riverina population of the Glossy Black-Cockatoo *Calyptorhynchus lathami* (Temminck 1807) are examples of Endangered Populations currently listed because of their morphologically distinct characteristics (Table 9).

Ecologically distinct populations display life history or behavioural traits or habitat relationships that are distinctive or unique relative to the wider population of the species. For example, the Black Cypress Pine population on the Woronora Plateau occurs at a site that receives more than double the mean annual rainfall than other extant parts of the species distribution (Mackenzie & Keith 2009). In addition, this example would also qualify as being of significant conservation value as it occupies a unique environmental niche for the species and this may provide adaptive capacity for the species under changing environmental conditions.

Where a population is disjunct or at the edge of the species range, it would still need to be demonstrated that the population is significant in the conservation of the species. Disjunct populations may imply a substantial level of demographic and genetic isolation from other individuals of the species (i.e. greater isolation than is required for a group of conspecific organisms to be recognised as a population). With reference to IUCN’s (2001) definition of a subpopulation, the level of isolation required for a disjunct population would need to entail less than a ‘little demographic or genetic exchange with other populations of the species’. The geographic distances associated with this isolation will vary between species, depending on life history, dispersal and breeding behaviour. For listed plant and animal populations, identified disjunctions vary from the order of tens to hundreds of kilometres. In some cases, dispersal barriers such as topographic features, water bodies, roads or other stretches of unsuitable habitat have been identified as factors contributing to the disjunct status of listed populations.

Climate refugia will become increasingly important as climate change causes an increased frequency and intensity of extreme events, such as drought. Floodplains are potential drought refugia because they have cooler and more mesic microclimates than adjacent areas, and greater water availability through shallower groundwater and flooding (Selwood et al. 2015). Moist, montane forests also offer the potential to provide climate refugia (Milstead et al. 2007; Mackey et al. 2012; Reside et al. 2014). Fire refuges provide other ecologically important areas for populations of some species.
Examples of currently listed populations that would qualify as being significant for the species are listed in Table 9.

**Table 9.** Examples of threatened populations that are significant for the species.

3.2.2 **Populations that make significant contributions to the conservation of other species**

Populations may make a significant contribution to the conservation of other species, as they may aid the conservation of key dispersal agents, pollinators, apex predators, ecosystem engineers, elements of habitat structure, or other elements that are important to the survival of other species. Examples of currently listed populations that would qualify as making significant contributions to the conservation of other species are listed in Table 10.

**Table 10.** Examples of threatened populations that are considered to be significant for the conservation of other species.

4 Assessments of Ecological Communities

Nominations of ecological communities for listing as threatened under the BC Act 2016 must be assessed under Clauses 4.7-4.14 of the BC Regulation 2017. An ecological community is eligible for listing if it meets any one of these clauses.

4.1 Definition of an ecological community

The BC Act (section 1.6) defines an ecological community as ‘an assemblage of species occupying a particular area’. This definition closely follows modern scientific texts (e.g. Begon et al. 2006) and embodies three requirements (Preston & Adam 2004a):

i) the constituents of a community must be species;
ii) the species need to be brought together into an assemblage; and
iii) the assemblage of species must occupy a particular area.

4.1.1 Constituent species

Section 1.6 of the Act adopts a pragmatic and inclusive definition of a species as including ‘any defined sub-species and taxon below subspecies and any recognisable variant of a sub-species or taxon.’ The Act does not require such variants to have been formally described, only that they be recognisable. Appropriate taxonomic specialists and institutions should be consulted to determine whether any particular variant of a species or subspecies is recognisable.

Terrestrial ecological communities are often conveniently described by nominating characteristic vascular plant species, as plants are typically the most detectable species of an assemblage. However, this does not preclude descriptions of ecological communities based on other taxonomic groups. For example, ecological communities have been listed under the BC Act based primarily on descriptions that include birds, lichens, fungi and snails/slugs. Many currently listed ecological communities described primarily by reference to their plant species composition, also mention vertebrate and invertebrate species, but note that these components are usually poorly documented.

4.1.2 Assemblage of species

An assemblage of species involves the bringing together or gathering into a location or locations the identified species (Preston & Adam 2004a). The ecological concept of a community also involves interactions between the constituent species (Whittaker 1975), although this is not explicitly mentioned in the definition in the BC Act. Interactions between at least some of the species within a community are implicit in their co-occurrence (Keith 2009).

The BC Act (Section 4.16(3)) provides for challenges to listings for up to six months after publication of Final Determinations. One potential avenue of challenge concerns whether a particular listing meets the definition of an Ecological Community under the Act. Legal action challenging the efficacy of one listing, heard by the Land and Environment Court with subsequent appeal heard by the Supreme Court of NSW (VAW Kurri Kurri vs NSW Scientific Committee), established important precedents in the interpretation of ecological communities (Preston & Adam 2004a,b). Review of the efficacy of the ‘assemblage of species’ is therefore an essential requirement for evaluation of all nominations of ecological communities.
The notion of species co-occurrence is central to the existence of an assemblage of species. An important aspect of co-occurrence is the notion that a common, albeit variable, group of species occurs within the distribution of a community. Structurally dominant species, those most abundant or with greatest height or biomass, are sometimes used as abbreviated descriptions of assemblages. However, the occurrence of one or two dominant species, of itself, is not evidence of the existence of an ecological community. Moreover, such an approach assumes a discrete model of ecological communities (see Box 6 for graphical illustration) in which all or most species show highly correlated co-occurrence with the dominants. Such models are unlikely to hold true (Box 6, Begon et al. 2006, Keith 2009). Hence, ‘communities’ defined solely on the basis of dominant species may be poor representations of the broader assemblage of species in which those species are ‘dominant’. This is because the same assemblage may sometimes be dominated by other species and because the nominated dominants may sometimes be part of other assemblages. For these reasons, the emphasis of description and diagnosis of ecological communities should address overall species composition of the assemblage, rather than occurrence of selected species (dominant or otherwise). Preston & Adam (2004a) further reinforce the importance of overall species composition in the classification of communities,

‘Given the primary stress in the definition of ecological community in the TSC Act on an assemblage of species, approaches to vegetation description and classification that involve assessment of total floristics are clearly desirable.’
Box 6. The nature of ecological communities (from Keith 2009)

Figure 1 from Keith (2009): Alternative models of ecological communities showing variation in abundance of component species along a simple environmental gradient (after Austin 1985). (a) Organismal discrete model (Clements 1916). (b) Individualistic continuum model (Gleason 1926). The alternative models have different implications for the status of dominant species, which always offer accurate representation of community occurrence under the Clementsian model, but not necessarily under the Gleasonian model (Fig. 1). Under the latter, communities can rarely be identified conclusively based on their dominant species alone. The modern view of ecological communities is closer to the continuum model than the discrete one, although there is broad recognition that species are not distributed completely independently of one another (Austin & Smith 1989; Burrows 1990; Begon et al. 2006). Thus, a given location, by virtue of its physical characteristics, may be expected to support a reasonably predictable assemblage of species; but there is variability in the group of species actually present, vagueness in boundary location and overlapping membership of species between different assemblages (Begon et al. 2006). These patterns of variability are not well represented in a discrete system that demands recognition and ready identification of communities as distinct entities. While spatial scale may influence how overlapping species distributions are perceived, communities are not necessarily any more discrete at larger or smaller scales. See Keith (2009) for further discussion of the issue.

Unlike species, there is no currently accepted typology of ecological communities (Preston & Adam 2004a). Even where such typologies exist or are under construction (e.g. Rodwell et al. 2002; Benson 2006), they will inevitably be subject to constraints and limitations associated with available data, methods, biases and knowledge gaps, and therefore may not represent the existence of particular ecological communities. This necessitates the use of a variety of approaches to examine the efficacy of nominated communities. If a given community can be verified by independent methods or several independent means, this provides reasonable evidence of its efficacy. This may also require amalgamation of different types of data in order to develop a workable description of an ecological community (Preston & Adam 2004a).
While not an essential basis for listing ecological communities, numerical analyses of compositional data can often provide stronger evidence for the efficacy of a community than other approaches. This is because the information contributing to a community description is explicit in the input data set, the assumptions and logic of the methods are transparent, and inferences drawn from the output can be justified. Methods that may provide relevant insights include: cluster analysis, ordination, analysis of similarity, fidelity analysis, similarity components analysis, etc. (Belbin 1993, Clarke & Warwick 1994). The Committee has reviewed a number of such analyses (published and unpublished) to assess the efficacy of nominated communities and has also undertaken meta-analyses to test the efficacy of a number of nominated communities (Table 11).

The review process needs to examine whether the methods have been validly applied and the outputs validly interpreted. It also needs to examine whether the input data have been adequately proofed and edited (where necessary) to ensure consistency of species nomenclature and abundance estimates. These issues are discussed further in Section 4.2.1.

Ecological communities exist at a range of thematic, spatial and temporal scales. It is axiomatic that any community comprises two or more other communities, which are defined at finer levels of organisation (Keith 2009, Box 7). The BC Act does not specify any requirement for ecological communities to be defined at any particular scale in order to be eligible for listing. Preston & Adam (2004a) note that ‘it is possible to satisfy the three requirements [in the definition of an ecological community] at various levels of specificity [thematic scales] and spatial scales.’ This provides important flexibility in the listing of communities at a range of scales to cover the diversity of assemblages in nature and deal with the processes that threaten them, also at a range of scales. Nicholson et al. (2009) suggest that there are economies in listing communities at the broadest scale at which they meet criteria for listing (see Box 7). Keith (2009) includes further discussion of the concepts and community theory relevant to definition and description of ecological communities.
**Box 7. Ecological communities at different scales.**

From Keith (2009). Two different representations of thematic scale in hierarchical classifications of ecological communities. (a) A Venn diagram showing 14 fine-scale communities nested within each of seven meso-scale communities nested within each of three coarse-scale communities. (b) A dendrogram showing 13 communities recognised at fine scale (low dissimilarity or high level of resemblance), 10 communities at meso-scale (intermediate dissimilarity) and five communities recognised at coarse scale (high dissimilarity).
From Nicholson et al. (2009). A hypothetical classification of ecological assemblages showing three alternative approaches for dealing with thematic scale in assessment. First, at a fixed fine scale of assessment, there are 13 communities, of which eight are threatened due to high rates of decline (black squares). Second, at a fixed coarse scale, there are five broader communities (I-V). Of these, communities II and IV are clearly threatened because all of the finer scale assemblages within them are declining at a rate exceeding the specified threshold (they contain only black squares), while community V is not threatened (contains only assemblage 13). However, the status of communities I and III is uncertain because they contain mixtures of threatened and non-threatened communities. Their status could therefore be determined by an area-weighted average rate of decline. Finally, under a flexible scale of assessment, communities A, B, C and D are threatened (contain only black squares), while the remaining assemblages are not threatened. Note that communities A and C are identical to fine communities 1 and 9, respectively, while communities B and D are identical to broad communities II and IV, respectively. Flexibility in the scale of assessment will be more limited for assessments based on only distribution size criteria (cf. decline criteria). For example, the broad community IV would only qualify for threatened status under the area criterion if the combined areas of finer communities 11 and 12 did not exceed the area threshold, irrespective of whether the distributions of communities 11 and 12 are individually smaller than the threshold.

4.1.3 Particular area
The particular area defines the location(s) at which species of the assemblage co-occur. According to Preston & Adam (2004a), this represents the ‘natural habitat in which the
assemblage of species occurs or has historically occurred and is capable of recurring if measures are taken to restore or allow the habitat to recover.’ It therefore excludes captive or cultivated occurrences because they are not within the ‘natural habitat’ of the community. In Determinations, the particular area of an ecological community is often described by identifying the bioregions in which it occurs (see Section 4.2.2).

4.2 Description of an ecological community

Descriptions of ecological communities have multiple roles in listing statements or determinations, where they support regulatory, conservation and recovery operations, as well as legal actions (Keith 2009). First, they provide for scientific diagnosis of communities, and thus identify instances where regulatory protocols and conservation actions are triggered. Second, they may be required to articulate a scientific justification for listing of the communities. Third, they are legal documents that support compliance, enforcement and prosecution under laws that protect the listed communities. Fourth, they are a means of alerting the public to the existence of threatened communities, and hence the need to seek specialist advice to confirm diagnosis of the community and to determine how laws and regulations may apply to management of particular land parcels.

Preston & Adam (2004a) outline the legal and practical requirements for a description of an ecological community under threatened species legislation in NSW. There are three legal requirements of a description, which are implicit in the statutory definition of an ecological community (see section 4.1). In addition to the legal requirements for a description of an ecological community (section 4.1) there is a practical requirement that the description be ‘interpretable by a reasonably well-informed lay person, at least to the extent of knowing they need to seek professional advice’ (Preston & Adam 2004a).

The multiple roles of determinations sometimes necessitate trade-offs in the content and form of community descriptions (Keith 2009). For example, a requirement for simplified expression of the key features of a community to inform ‘lay persons’ might not include sufficient detail or caveats to support a rigorous scientific diagnosis of a community. Similar trade-offs apply to the flexibility of community descriptions. Flexibility that acknowledges some degree of uncertainty is essential in the description of a community to accommodate the natural variability in its properties (Preston & Adam 2004a). Too much flexibility may be seen as precluding identification of a community with sufficient certainty to support regulatory and legal actions, but an overly prescriptive description may fail to identify many examples of the species assemblage that the listing is designed to protect (Regan et al. 2002). The NSW Courts have taken a pragmatic approach to uncertainty. Chief Justice Spigelman1 of the Supreme Court in NSW stated:

“The use of the word ‘assemblage’ does not suggest that either the nomination of species or identification of an area requires a high degree of specificity... The intricacy of all ecological communities means that some indeterminateness is bound to arise from the form of expression used to describe them.”

The NSW Threatened Species Scientific Committee has developed a format for listing of threatened ecological communities that contains the following elements:

Parts 1 & 2: Section 1.6 of the Act defines an ecological community as “an assemblage of species occupying a particular area”. These features of an ecological community are described in Parts 1 and 2 of this Determination, respectively.

Part 3: Part 3 of the Determination describes the eligibility for listing of the ecological community in Schedule 2 of the Act according to criteria as prescribed by the Biodiversity Conservation Regulation 2017.

Part 4: Part 4 of the Determination provides additional information intended to aid recognition of this community in the field. Rather than being diagnostic, information in Part 4 is a guide to assist recognition and given natural variability, along with disturbance history, the ecological community may sometimes occur outside the typical range of variation in the features described in Part 4.

4.2.1 Describing the assemblage of species

Part 1 of the current format of NSW Threatened Species Scientific Committee determinations provides details on the assemblage of species in an ecological community. The description of an ecological community should include a list of characteristic constituent species. The construction of the list of characteristic species will depend on available information (e.g. qualitative descriptions cf. quantitative floristic data), and will vary from case to case (see Preston & Adam 2004a). However, descriptions would usually aim to include frequently occurring species, those that may be locally abundant, though not necessarily present throughout the distribution of the community, and species whose occurrence may help to distinguish the community from other similar communities (where that information is available). It may also be appropriate to list rare or threatened species to draw attention to their occurrence within the community. In some cases, it may be appropriate to subdivide the list of characteristic species to make it clear which species are likely to occur frequently throughout the community distribution (e.g. see Final Determination of Sandhill Pine Woodland in the Riverina, Murray-Darling Depression and NSW South Western Slopes bioregions).

Ideally, there should be a clear rationale for including any given species in the list of characteristic species that describes a listed ecological community. This rationale will depend on the nature of available data on constituent species, which varies from case to case. For example, in some cases, the entire distribution of a nominated community is covered by a systematic ecological survey (e.g. Cumberland Plain Woodland, Tozer 2003) or it may be possible to carry out such an analysis as part of the assessment of a nominated community (see section 4.1.2). Where this includes systematic sampling of species composition, it may be appropriate to select species for inclusion in the description if their frequency of occurrence within plots assigned to the community exceeds a given threshold. Inclusion of less frequent species may also be warranted if they exhibit high fidelity with the nominated community (cf. other communities). Suitable thresholds for frequency and fidelity will vary depending on the level of sampling and species richness of the community. Where quantitative compositional data are unavailable or provide only partial coverage, an alternative rationale is needed.
For example, several independent qualitative descriptions or species lists may be available for different or overlapping parts of the community distribution. It may be appropriate to compile a list of characteristic species from those that occur most frequently across those multiple sources.

Given the inherent spatial and temporal variability in ecological communities and limited detectability of some species (e.g. species that may, at times, only be present below ground as seeds or rootstocks etc), the list of characteristic species will be a sample of the total number that comprise the community. The NSW courts have recognised the impracticality of providing a complete enumeration of all constituent species in a community (Preston & Adam 2004a). Nonetheless, appropriate caveats on the interpretation of such a list should be included in Determinations of ecological communities (Box 8).

**Box 8. Example text explaining caveats on the list of characteristic species describing ecological communities listed under the BC Act.**

The total species list of the community across all occurrences is likely to be considerably larger than that given above. Due to variation across the range of the community, not all of the above species are present at every site and many sites may also contain species not listed above.

Characteristic species may be abundant or rare and comprise only a subset of the complete list of species recorded in known examples of the community. Some characteristic species show a high fidelity (are relatively restricted) to the community, but may also occur in other communities, while others are more typically found in a range of communities.

The number and identity of species recorded at a site is a function of sampling scale and effort. In general, the number of species recorded is likely to increase with the size of the site and there is a greater possibility of recording species that are rare in the landscape.

Species presence and relative abundance (dominance) will vary from site to site as a function of environmental factors such as soil properties (chemical composition, texture, depth, drainage), topography, climate, and through time as a function of disturbance (e.g. fire, logging, grazing) and weather (e.g. flooding, drought, extreme heat or cold).

At any one time, above ground individuals of some species may be absent, but the species may be represented below ground in the soil seed bank or as dormant structures such as bulbs, corms, rhizomes, rootstocks or lignotubers.

The species listed above are vascular plants, however the community also includes micro-organisms, fungi and cryptogamic plants as well as vertebrate and invertebrate fauna. These components of the community are less well documented.

Patterns of species co-occurrence may sometimes be complex and recognisable at a range of spatial, thematic and temporal scales (Keith 2009). As mentioned above, multi-
variate analyses of species composition, where adequate data are available, may assist in resolving descriptions of ecological communities (Kendall & Snelson 2009). Given the emphasis on assemblages of species in the BC Act, quantitative approaches that address overall species composition are clearly desirable (Preston & Adam 2004a). In vegetation science, for example, the Zurich-Montpellier system is an internationally established approach to the classification of species assemblages, the principles of which are applicable to any biological system (Muller-Dombois & Elenberg 1974, Bridgewater 1981). A rigorous analysis of this sort will usually require evaluation and ‘quality control’ of the data (e.g. Keith & Bedward 1999) and supplementary analyses to assess the likelihood that the results are influenced by artefacts in the data or coverage of samples. The standardisation of taxonomic nomenclature, removal of indeterminate taxa and standardisation of abundance measures are three common pre-requisites, particularly for meta-analyses that draw data from multiple sources. Keith & Bedward (1999), Tozer et al. (2010) and recent examples of such applications include Keith & Scott (2006), Mackenzie & Keith (2007), NSW Scientific Committee & Mackenzie (2008), Soderquist & Irvin (2008) and others listed in Table 11.

In addition to listing the characteristic species of the assemblage, a Determination of an ecological community may include a text description that incorporates features such as the relative abundance, dominance, growth forms, vertical stratum and geographic occurrence of component species. These components are included in Part 4 (additional information) of the determination. Box 9 provides an example description incorporating these features.

**Box 9. Example of a text description of an ecological community (from the Final Determination of Sandhill Pine Woodland as an Endangered Ecological Community).**

Sandhill Pine Woodland is characterised by an open tree stratum, which may be reduced to isolated individuals or may be absent as a result of past clearing. The tree layer is dominated by *Callitris glaucophylla* (White Cypress Pine), either in pure stands or with a range of other less abundant trees or tall shrubs. These may include *Acacia melvillei*, *A. oswaldii*, *Allocasuarina luehmannii* (Buloke), *Callitris gracilis* subsp. *murrayensis* (Slender Cypress Pine), *Hakea leucomeris* (Needlewood), *H. tephroserma* (Hooked Needlewood), *Myoporum platycarpum* (Sugarwood) and *Pittosporum angustifolium* (Berrigan). A scattered shrub layer is sometimes present and may include *Dodonaea viscosa* subsp. *angustifolia*, *Enchylaena tomentosa* (Ruby Saltbush), *Sclerolaena muricata* (Black Rolypoly) and/or *Maireana enchylaenoides* (bluebush). The groundcover is highly variable in structure and composition. It may be sparse or more continuous, depending on the history of disturbance, grazing and rainfall events. It comprises grasses, such as *Austrodanthonia caespitosa* (Ringed Wallaby Grass), *A. setacea* (Small-flowered Wallaby Grass), *Austrostipa nodosa* (a speargrass), *A. scabra* (Rough Speargrass), *Enteropogon acicularis* (Curly Windmill Grass), *Panicum effusum* and *Paspalidium constrictum*; and forbs including *Atriplex semibaccata* (Creeping Saltbush), *Einadia nutans* (Climbing Saltbush), *Erodium crinatum* (Blue Storksbill), *Oxalis perennans*, *Sida corrugata* (Corrugated Sida) and *Wahlenbergia* spp. (bluebells). The structure of the community varies depending on past and current disturbances, particularly clearing, logging, grazing and soil erosion.
4.2.2 **Describing the particular area**

Part 2 of the current format of the NSW Threatened Species Scientific Committee determinations provides details on the particular area occupied by an ecological community. The ‘particular area’ occupied by an ecological community needs to be described with reasonable specificity, but need not be highly prescriptive (Preston & Adam 2004a). In NSW, the Land and Environment Court and the Court of Appeal have held that it is sufficient to specify the bioregions in which a community occurs and the local government areas in which it has been recorded (Preston & Adam 2004a). Consequently, for most ecological communities listed in NSW, the ‘particular area’ is defined by one or more bioregions (as described by SEWPaC (2012) or in older determinations, Thackway & Creswell 1995), which are usually incorporated into the name of the community. The bioregions in which a community occurs are currently detailed in Part 2 (particular area occupied by the ecological community) of current format determinations, while also information relating to Local Government Areas in which the community occurs is provided in Part 4 (additional information). In the past, information relating to Local Government Areas was included to assist regulatory applications under the BC Act but was not intended to be exhaustive and it was intended as implicit that the community may be recorded in other LGAs as knowledge of its distribution develops. It is not currently the policy of the NSW Threatened Species Scientific Committee to include information relating to LGAs because this has caused confusion as to what constitutes the legal definition of the area occupied by ecological communities.

Although not legally required, information about ‘supplementary descriptors’ (section 4.2.3, Part 4 of the current format of NSW Threatened Species Scientific Committee) determinations details additional information about the ecological community which may also assist in the interpretation of the particular area occupied by an ecological community. For example, environmental conditions such as the typical climate, terrain, substrates and other abiotic, biotic or ecological factors with which the community is associated can assist in drawing inferences about its likely occurrence at particular locations (Preston & Adam 2004b). However, supplementary descriptors must be regarded as a useful adjunct, rather than a substitute for a description of the particular area occupied by a community (Preston & Adam 2004b).

The NSW Land and Environment Court and the Court of Appeal have held that maps showing the distribution of an ecological community are not an essential legal requirement for describing the particular area in which they are found (Preston & Adam 2004a). Mapped boundaries of communities are subject to a range of uncertainties (Keith 2009), commonly mis-interpreted, and generally unsuitable for a definitive delineation of areas subject to listings under the BC Act. Consequently, with the exception of highly localised assemblages, maps are rarely included as part of Determinations of ecological communities to avoid overly prescriptive mis-interpretations of the ‘particular area’ of occurrence.

Despite their limitations, maps can provide indicative guidance on distribution of ecological communities and useful data for assessing their status (see section 4.3.1). To provide non-prescriptive guidance, many Determinations therefore make reference to studies (if available) that map the distributions of units that are related to the listed ecological community. The nature of the relationship between the listed community and the mapped unit will determine how the map can inform about the particular area
NSW Threatened Species Scientific Committee  
Biodiversity Conservation Act Listing guidelines version 2.0, March 2018

of the listed community and this varies from case to case. Sometimes, the listed community corresponds directly with the mapped unit. In other cases, the mapped unit is part of the listed community, or the listed community may be included within a broader mapped unit. The reference to relevant mapping studies, rather than direct incorporation of maps as part of Determinations, readily accommodates corrections and updates and reduces uncertainty in cases where published scientific literature is used as reference material, as this is subject to scientific peer review.

4.2.3 **Supplementary descriptors**

Part 4 of the current format of NSW Threatened Species Scientific Committee determinations deals with additional information about the ecological community. Preston & Adam (2004b) identify ‘supplementary descriptors’ that may assist interpretation, providing greater certainty to the description of a community and permitting easier recognition in the field. Structural features are examples of supplementary descriptors of the community mentioned in Box 8. Structural features include the vertical and horizontal spatial arrangement of individual organisms within the community (Keith 2009). Other supplementary descriptors include the following:

- physiognomic features of a community (e.g. the texture, size and orientation of leaves, and the range of life forms in a plant community)
- relationships of the community to abiotic factors (e.g. the climate, landforms, hydrological features and substrates that define the environmental conditions in which the community occurs);
- other biotic features (e.g. interactions between component species, responses to processes such as herbivory, etc.); and
- dynamic features (e.g. relationships to disturbance regimes, successional properties, etc.).

As with other features of a community, its structure, physiognomy, relationships with abiotic factors, biotic and dynamic features may be variable and uncertain. Consequently, appropriate qualifiers should be used to describe these features. In some cases, it may be possible to describe the nature of variation. Box 10 includes an example of reference to the variation in a number of supplementary descriptors of an ecological community. The phrases underlined illustrate the indicative, rather than prescriptive intent of the information provided on supplementary descriptors.

**Box 10. Extract from the Final Determination of Lowland grassy woodland of the South East Corner bioregion, including reference to supplementary descriptors.**

Lowland Grassy Woodland in the South East Corner bioregion is the name given to the ecological community associated with rainshadow areas of the south coast and hinterland of New South Wales. These rainshadow areas receive less rainfall than more elevated terrain that partially surrounds them, with mean annual rainfall typically in the range of 700-1100 mm. The community typically occurs in undulating terrain up to 500 m elevation on granitic substrates (e.g. adamellites, granites, granodiorites, gabbros, etc.) but may also occur on locally steep sites and on acid volcanic, alluvial and fine-grained sedimentary substrates. Lowland Grassy Woodland in the South East Corner bioregion is characterised by the assemblage of species listed in paragraph 2 and typically comprises an open tree canopy, a near-continuous groundcover dominated by grasses and herbs, sometimes with layers of shrubs and/or small trees. Undisturbed stands of the community may have a woodland or forest structure. Small trees or
saplings may dominate the community in relatively high densities after partial or total clearing. The community also includes ‘derived’ native grasslands which result from removal of the woody strata from the woodlands and forests.

The question of whether supplementary descriptors can be determinative regarding the occurrence of a listed community at a given location has been controversial. Some environmental consultants have argued that a listed community cannot be present at a site if the features of the site do not match the supplementary descriptors in the Final Determination, irrespective of whether the assemblage of species and particular area match those described in the Final Determination (e.g. NSWLEC 102\(^2\)). This determinative interpretation is rarely consistent with the NSW TSSC’s intent in providing information about supplementary descriptors to assist identification of a community. Courts have generally taken a broad (non-determinative) interpretation of supplementary descriptors (e.g. NSWLEC 297\(^1\) - VAW Kurri Kurri vs Scientific Committee 2003, NSWLEC 770\(^3\)). Preston & Adam (2004b) stress that supplementary descriptors…

“cannot be used as a substitute for a description of the assemblage of species and the particular area in which the community is located. Rather they should be seen as a valuable adjunct.”

This reasoning stems from the statutory definition of an ecological community. Nonetheless determinative interpretations of supplementary descriptors continue to be presented (e.g. NSWLEC 102\(^2\)), and it is important that wording of Determinations gives guidance as to whether a broad interpretation is intended.

4.3 **Clause 4.9 – reduction in geographic distribution**

Reductions in geographic distribution are one of the key symptoms of extinction risk for ecological communities (Rodriguez *et al.* 2007; Nicholson *et al.* 2009, Keith *et al.* 2013). Ecological communities that have undergone large reductions, or are likely to undergo large reductions in the future, are generally exposed to greater risks of collapse (see Keith *et al.* 2013 for a description of the concept of ecosystem collapse) than those that have undergone or are likely to undergo smaller reductions, or unlikely to undergo any reduction. Furthermore, a significant reduction in geographic distribution almost certainly entails a significant loss of diversity in the community, particularly in communities with strong spatial structure and component species with limited dispersal abilities. Clause 4.9 specifies varying levels of reduction as eligibility criteria for listing in respective categories of threat, and is therefore analogous to Clause 4.2 for the assessment of species. Interpretation of the two clauses must therefore be logically

consistent, and much of the interpretive guidance for Clause 4.2 is relevant to the interpretation of Clause 4.9. To be eligible for listing under Clause 4.9, communities that have undergone a sufficiently large reduction within the relevant past time frame need not exhibit evidence of a continuing decline.

4.3.1 Estimating reduction in distribution
Estimating the reduction in the geographic distribution of an ecological community for assessment under Clauses 4.9 will usually require spatial data from which the mapped extent of the community can be determined at two or more points in time. Most commonly, temporal reference point for mapping will include a contemporary distribution and an historic distribution that has been projected (by various means) to a point just prior to European settlement. Prior to estimating reduction in distribution, it is necessary to assess the assumptions and methods used to project the historic distribution of the ecological community. Further assumptions and mathematical interpolations are then required to calculate reductions over the time period relevant to assessment of Clause 4.9 (see Section 4.3.3). The sensitivity of the assessment outcome to both assumptions and the method of interpolation should be assessed by recalculating reduction rates under different scenarios (assumptions and methods) corresponding to the main sources of uncertainty. The map data can be used directly to estimate a reduction where one or more map unit(s) correspond(s) directly with the ecological community (section 4.2.2). Where there is an indirect relationship (e.g. the distribution of the ecological community is incompletely represented by the map unit(s)) further spatial analysis may be required, given plausible assumptions about the maximum and minimum likely extent of the community. In some cases, it may be prudent to combine spatial data from two or more different mapping studies that cover different parts of the community’s distribution. Keith et al. (2009) and Keith et al. (2013) outline a detailed protocol with worked examples for estimating changes in distributions of ecological communities. An important aspect of the protocol is to calculate reductions for a set of scenarios that cover a plausible range of assumptions about the relationships between the map data and the distribution of the community. Different cases are likely to require different sets of scenarios and different assumptions which require evaluation and justification on a case by case basis.

Where spatial data on the distribution of an ecological community are unavailable or incomplete, it may be possible to infer reductions from proxy spatial data. For example, maps of land use may allow inferences to be drawn about the area of land within the distribution of a community that has been converted to urban or agricultural uses.

4.3.2 Magnitude of reductions in distribution
To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, an ecological community must have undergone or be projected to undergo a very large (Subclause 4.9a), large (Subclause 4.9b) or moderate (Subclause 4.9c) reduction. Keith et al. (2013) have developed the IUCN red list criteria for ecosystems and these represent the internationally accepted criteria for assessing the status of ecological communities. Nicholson et al. (2009), reviewing twelve assessment protocols developed in different countries, found considerable variation in quantitative thresholds of reduction and little or no evidence of a clear rationale for the thresholds applied in each case. Keith et al. (2013) have proposed thresholds for decline and these
largely reflect the IUCN (2001) species thresholds. Guidelines for use of these thresholds can be found in Bland et al. (2017).

For the purpose of interpreting Clause 4.9, the corresponding listing criteria in Bland et al. (2017) provide indicative guidance for quantitative interpretation of these terms (Table 12). Reductions in geographic distribution may be interpreted under A1, A2a and A2b (Bland et al. 2017) if reductions are over the past 50 years, the next 50 years, or any 50 year period including the past, present and future. Reductions in geographic distribution should be interpreted under A3 (Bland et al. 2017) where the reduction is historical reduction since 1750.

Table 12. Corresponding thresholds for reductions in geographic distribution for ecological communities for the BC Regulation 2017 and IUCN Red List criteria for ecosystems (Bland et al. 2017). Reductions in geographic distribution may be interpreted under A1, A2a and A2b (Bland et al. 2017) if reductions are over the past 50 years, the next 50 years, or any 50 year period including the past, present and future. Reductions in geographic distribution should be interpreted under A3 (Bland et al. 2017) where the reduction is historical reduction since 1750.

4.3.3 Time frames for assessing reductions in distribution

Reductions in the distribution of an ecological community must be assessed over a 50 year time span or since 1750. For many terrestrial plant communities, historical distributions have been reconstructed using quantitatively or intuitively derived relationships between the occurrence of a community and environmental variables for which spatial data are available (e.g. Keith & Bedward 1999).

4.3.4 Influence of spatial scale

The spatial scale of map data will influence estimates of reduction in distribution. Finer-scale maps will be more proficient than coarse-scale maps at detecting small patches from which the community has disappeared and other small patches in which the community remains extant. For this reason, it is important that chronosequential maps used in temporal analysis to estimate reductions are at similar spatial scales and resolution. If this is not the case, then it is advisable to convert the finer-scale map(s) to the scale of the coarser map(s), even though this may involve loss of information from the finer-scale map(s). Scale standardisation will reduce any scale-related artefacts in estimates of change based on the map data. In contrast to estimates of area (section 4.4.2, Box 5), estimates of change are unlikely to be very sensitive to the actual scale of maps used in assessment, so long as the chronosequential maps are of a scale consistent with one another. However, where relevant spatial data sets are available at a variety scales, it is advisable to use the finest available spatial data that is
common to both chronological reference points to obtain estimates with the highest level of precision.

4.3.5 **Calculating reductions in distribution**

Bland *et al.* (2017) provide extensive advice methods for assessing reductions in the geographic distribution of ecological communities.

Reductions should be averaged across the entire distribution of a community. The extent of a community may be changing at different rates in different parts of its distribution. Where changes in distribution have been sampled in different parts of a community’s distribution, the changes should be weighted by the extent of the community at the beginning of the assessment period in each sampled area. For example, declines in areas with extensive occurrences of the community will outweigh increases or stability in areas with small occurrences. Box 3 and IUCN (2017) give example calculations for species, while Keith *et al.* (2009) demonstrate a similar application for an ecological community. Where spatial data on reduction are only available for part of the distribution of the community, an inference about the level of reduction across the entire distribution will depend on plausible assumptions about whether the reduction observed in the sampled area is likely to be representative of more general trends. This will usually involve reference to the causes and mechanisms that are driving the reduction.

Available data on reductions in the distribution of a community may not correspond to the required 50 year or historical (since 1750) timeframes over which reductions must be assessed against the listing criteria. For example, estimates may be available for reductions that occurred over the last 30 years (where remote imagery is available), but reductions may need to be assessed over a 50 year time frame. Analogous situations may arise in species (see section 2.1.7 & Box 3). In such cases, interpolation or extrapolation may be required where the data are available for a longer or shorter period than the required time frame for assessing reductions. In both cases, the best approach is to fit a regression model to the available data and use the appropriate time interval on the fitted line to calculate the reduction. Fitting a model in this way helps to eliminate some of the variability that may be attributable to short-term causes. Interpolation or extrapolation will require assumptions about the data and the trend that should be justified with reference to the processes driving the decline (e.g. pattern of land use change). For example, depending on the shape of the data, a linear or exponential regression model may be fitted. Keith *et al.* (2009) provide an example in which future reductions are projected assuming alternative linear and exponential patterns of future decline. Assumptions about the rate of decline remaining constant, increasing or decreasing, relative to the observed interval must be justified, especially where the reduction in distribution is estimated over long times from data over shorter time frames. Bland *et al.* (2017) note that whether inferences are made from time series of satellite images or from other data sources, two important aspects will fundamentally influence assessments: (i) assumptions about the rate of decline; (ii) the number of points in the time series. When the rate of decline is estimated from two observations (e.g. maps) over a specified time frame, information about the causes and context of the decline should be used to deduce the likely trajectory (see Fig. 9 in Bland *et al.* (2017)).
4.4 Clause 4.10 – size of geographic distribution

An ecological community will be eligible for listing as threatened under Clause 4.10 if its geographic distribution is more restricted than a threshold extent; and it meets any one of the following conditions: there is a continuing decline; there are threatening processes that are likely to cause a continuing decline; or the ecological community exists at a low number of locations. Clause 4.10 is therefore analogous to Clause 4.4 for assessing the status of species and comparable with Keith et al. (2013). Ecological communities with restricted geographic distributions will have fewer opportunities for persistence because it is more likely that a single or small number of threatening processes or events will adversely affect the entire distribution. Conversely, the larger the distribution of a community, the more these risks of exposure to threats will be spread across different locations.

4.4.1 Geographic distribution

Geographic distribution is defined in Clause 4.18(1) of the BC Regulation 2017 as ‘the area or areas in which a species or ecological community occurs, excluding cases of vagrancy in species.’ Geographic distribution may be assessed in a number of different ways, including the extent of occurrence, area of occupancy and area of suitable habitat.

4.4.2 Measures of geographic distribution

Under Clause 4.10, the geographic distribution of an ecological community may be assessed by estimating the extent of occurrence, the area of occupancy or the area of suitable habitat. Each of these terms is defined in Clause 4.18(2).

(a) Extent of occurrence (EOO) is defined in Clause 4.18(2a) as the area of the total geographic range that includes all extant occurrences of the ecological community. Its application in Clause 4.10 follows criterion B1 in IUCN (2001) and more recently for ecosystems, B1 in Bland et al. (2017). Extent of occurrence can often be measured by a minimum convex polygon or convex hull (the smallest polygon in which no internal angle exceeds 180 degrees and which contains all the sites of occurrence). IUCN (2001) states that EOO may exclude discontinuities or disjunctions within the overall distributions of taxa (e.g. large areas of obviously unsuitable habitat). However, the consequences of excluding discontinuities vary, depending on whether the estimate of EOO is to be used for assessing the total distribution in Clause 4.10 or whether it is to be used for estimating or inferring reductions (Clause 4.9). To ensure consistency with the definition of Area of Occupancy (AOO), if EOO is less than AOO, EOO should be changed to make it equal to AOO. See Bland et al. (2017) for guidance on how to estimate EOO for ecosystems.

(b) Area of occupancy (AOO) is defined in Clause 4.18(2b) as the area within the total range (and hence within EOO) that is currently occupied by the community. It excludes unsuitable and unoccupied habitat. Its application in Clause 4.10 follows criterion B2 in IUCN (2001) and more recently for ecosystems, B2 in Bland et al. (2017). IUCN (2017) explains the rationale underpinning AOO as follows: “Suppose two species [or communities] have the same EOO, but different values for AOO, perhaps because one has more specialised habitat requirements. For example, two species [or communities] may be distributed across the same desert...
(hence EOO is the same), but one is wide ranging throughout (large AOO) while the other is restricted to oases (small AOO). The species [or community] with the smaller AOO may have a higher risk of extinction because threats to its restricted habitat (e.g. degradation of oases) are likely to reduce its habitat more rapidly to an area that cannot support viable populations of constituent species. The species [or community] with the smaller AOO is also likely to have smaller population sizes than the one with a larger AOO, and hence is likely to have higher extinction risks for that reason” (IUCN 2017). Estimates of AOO are highly sensitive to scale of measurement (Keith 2009, Nicholson et al. 2009, Bland et al. 2017). Bland et al. (2017) recommend that the AOO of an ecological community be determined by counting the number of 10×10 km grid cells that contain the ecological community. In summary, the area of occupancy of the community should be assessed at the standard assessment scale (10×10 km grid cells), for which the community’s distribution can be represented by occurrence uniform grid cells of appropriate size, irrespective of the format of the raw spatial data as polygons, grids, lines or points (see Box 5 and IUCN 2017). The standard assessment scale is determined essentially by the value of the thresholds that discriminate different categories of threat (Table 13). For this reason, it is often necessary to convert fine-scale mapping to a coarser scale for the purpose of assessing estimates of AOO against the thresholds. Electronic supplementary material available in Nicholson et al. (2009) gives examples of estimated areas of occupancy of communities at different spatial scales.

(c) **Area of suitable habitat** is defined in Clause 4.18(2c) as the area within the total range that includes occupied and unoccupied suitable habitat, but excludes unsuitable habitat. Maps of suitable habitat for communities may be derived (as those for species) from interpretation of remote imagery and/or analyses of spatial environmental data using simple combinations of GIS data layers, or by more formal statistical habitat models (e.g. generalised linear and additive models, decision trees, Bayesian models, regression trees, etc.). Habitat maps can provide a basis for estimating AOO and EOO and, if maps are available for different points in time, rates of change can be estimated (IUCN 2017, Bland et al. 2017). They cannot be used directly to estimate a community’s AOO because they often map an area that is larger than the occupied habitat (i.e. they also map areas of suitable habitat that may presently be unoccupied). However, they may be a useful means of estimating AOO indirectly, for which IUCN stipulates three conditions that must be met.

i) Maps must be justified as accurate representations of the habitat requirements of the community and validated by a means that is independent of the data used to construct them.

ii) The mapped area of suitable habitat must be interpreted to produce an estimate of the area of occupied habitat.

iii) The estimated area of occupied habitat derived from the map must be scaled to the grid size that is appropriate for AOO of the ecological community (i.e. 10 x 10 km grid).

Habitat maps can vary widely in quality and accuracy (condition i). A map may not be an accurate representation of habitat if key variables are omitted from the underlying model. For example, a map would over-estimate the habitat of a montane forest-community if it identified all forest areas as suitable habitat,
irrespective of altitude. The spatial resolution of habitat resources also affects how well maps can represent suitable habitat. For example, specialised edaphic, hydrological or physical habitat features, such as a flood regime or cliffs with particular moisture seepage regimes, may not lend themselves to mapping at coarse scales. Application of habitat maps to the assessment of communities for listing under the NSW BC Act, should therefore be subject to an appraisal of mapping limitations, which should lead to an understanding of whether the maps over-estimate or under-estimate the area of suitable habitat.

Habitat maps may accurately reflect the distribution of suitable habitat, but only a fraction of suitable habitat may be occupied (condition ii). Therefore the area of suitable habitat may be an upper bound of the possible AOO although, depending on the proportion of suitable habitat actually occupied, it could be substantially larger than any plausible upper bound of AOO. Low habitat occupancy may result because other factors are limiting – such as past disturbance, dispersal limitations, etc. In such cases, the area of mapped habitat could be substantially larger than AOO and will therefore need to be adjusted (using an estimate of the proportion of habitat occupied) to produce a valid estimate of AOO. This may be done by random sampling of suitable habitat grid cells, which would require multiple iterations to obtain a stable mean value of AOO (IUCN 2017).

Habitat maps are produced at a resolution determined by the input data layers (satellite images, digital elevation models, climate surfaces, etc.). Often these will be at finer scales than those required to estimate AOO (condition iii), and consequently scaling up will be required (see Box 5).

4.4.3 Size of geographic distribution

To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, an ecological community must have a geographic distribution that is estimated or inferred* to be very highly restricted (Subclause 4.10a), highly restricted (Subclause 4.10b) or moderately restricted (Subclause 4.10c) in addition to meeting the other condition relating to the action of a threatening process (section 4.4.4). Nicholson et al. (2009), reviewing twelve assessment protocols developed in different countries, found considerable variation in quantitative thresholds of geographic distribution and little or no evidence of a clear rationale for the thresholds applied in each case.

For the purpose of interpreting Clause 4.10, rather than setting arbitrary thresholds, it is recommended that Bland et al. (2017) thresholds for the geographic distributions of ecological communities be used (Table 13). The justification for this approach follows the same reasoning outlined in Section 4.3.2 for threshold reductions in geographic distribution. Further testing of the thresholds and scale of assessment developed by Keith et al. (2013) may warrant the future adoption of those measures.

* See Box 2 for definitions of ‘estimated’ and ‘inferred’
Table 13. Corresponding thresholds of geographic distribution size for the BC Regulation 2017 and the Bland et al. (2017) Red List for Ecosystems criteria. The recommended spatial scale for assessment is 10 x 10 km grid cells.

<table>

An ecological community that meets the requirements for very highly restricted, highly restricted or moderately restricted geographic distribution will only be eligible for listing under Clause 4.10 if and at least one of the following conditions apply:

4.10(d) there is a projected or continuing decline in any of the following:
   (i) a measure of spatial extent appropriate to the ecological community,
   (ii) a measure of environmental quality appropriate to the characteristic biota of the ecological community,
   (iii) a measure of disruption to biotic interactions appropriate to the characteristic biota of the ecological community,

4.10(e) there are threatening processes that are likely to cause continuing decline in either geographic distribution, environmental quality or biotic interactions within the near future,

4.10(f) the ecological community exists at:
   (i) for critically endangered ecological communities—an extremely low number of locations, or
   (ii) for endangered ecological communities—a very low number of locations, or
   (iii) for vulnerable ecological communities—a low number of locations.

4.4.4 Continuing decline

Continuing decline is a gradual or episodic decline in distribution or ecological process that is likely to continue into the future, and is non-trivial in magnitude and its effect on the sustainability of characteristic native biota (Bland et al. 2017). Only qualitative evidence of continuing decline is required to invoke this sub-criterion, but relatively high standards of evidence should be applied. Bland et al. (2017) note that to invoke this sub-criterion, the declines must: (i) reduce the ability of an ecological community to sustain its characteristicnative biota; (ii) be non-trivial in magnitude; and (iii) be more likely than not to continue into the future. Episodic or intermittent declines qualify as continuing, so long as they are recurring and uncompensated by increases of comparable magnitude. Downward phases of cyclical changes or
fluctuations do not qualify as continuing declines. These requirements imply an understanding of the causes of decline to support a correct inference.

To invoke this clause first requires identification and description of relevant threatening processes. One or more of these may be currently listed as Key Threatening Processes, and it will usually be appropriate to address the evidence for these in one or more dedicated paragraphs of a Determination. A second requirement is that the decline in extent or degradation in ecological function must be likely to continue into the future within the next two decades. These requirements imply an understanding of how the threats affect the defining features of the ecosystem and the timing of their effects. This evaluation of threats and associated declines and degradation may be qualitative and need not be quantitative, as required for reductions (Box 3).

4.4.5 number of locations

Subclause 4.10f requires an estimate of the number of threat-defined locations that are occupied relative to the extent of serious plausible threats. Bland et al. (2017) note that a threat-defined location is defined as a geographically or ecologically distinct area in which a single threatening event can rapidly affect all occurrences of an ecosystem type. Hence, a threat-defined location is not necessarily the same as a locality or site of occurrence; rather, a threat-defined location is defined entirely by the spatial extent of the most serious plausible threats (this is consistent with the definition of locations for The IUCN Red List of Threatened Species). The size of the threat-defined location depends on the area covered by the threatening event and may include part of one or many separate patches of the ecological community. Where an ecological community is affected by more than one threatening event, threat-defined locations should be defined by considering the most serious plausible threat (Bland et al. 2017). Where an ecological community is not affected by any threatening events, the number of threat-defined locations cannot be estimated and the subclause that refers to the number of locations will not be met.

For the purpose of interpreting Clause 4.10f, rather than setting arbitrary thresholds, it is recommended that Bland et al. (2017) thresholds for the number of locations be used (Table 14).

Table 14. Corresponding thresholds of number of locations for the BC Regulation 2017 Clause 4.10f and the Bland et al. (2017) Red List for Ecosystems criteria.

<table>

</tr>
</tbody>
</table>

4.5 Clause 4.14 Very small number of locations

To be eligible for listing as Vulnerable only, the number of locations of the ecological community must be such that the ecological community is prone to the effects of human activities or stochastic events within a very short period of time (Clause 4.14). The corresponding listing criteria in Bland et al. (2017), Criterion B3, applicable only for
listing as Vulnerable, states that there must be “generally fewer than 5” threat-defined locations. Threat-defined locations must be under severe and immediate threat, such that the ecological community is likely to collapse or is likely to become Critically Endangered in a very short period of time (Bland et al., 2017).

4.6 **Clauses 4.11 & 4.12 – Environmental degradation & disruption of biotic processes and interactions**

4.6.1 **Environmental degradation**

To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, an ecological community must have undergone or is likely to undergo within a time span appropriate to the life cycle and habitat characteristics of its component species a **very large degree of environmental degradation** (Subclause 4.11a), a **large degree of environmental degradation** (Subclause 4.11b) or a **moderate degree of environmental degradation** (Subclause 4.11c). Thresholds of environmental degradation may be interpreted under C1, C2a and C2b (Bland et al. 2017) if reductions are over the past 50 years, the next 50 years, or any 50 year period including the past, present and future (Table 15). Thresholds of environmental degradation should be interpreted under C3 (Bland et al. 2017) where the reduction is historical reduction since 1750. The corresponding listing criteria (Bland et al. 2017) are a matrix of both severity and extent and to meet the thresholds these two components should meet the quantitative threshold. Relative severity is the estimated magnitude of past or future environmental degradation, expressed as a percentage relative to a change large enough to cause ecosystem collapse. Note that there must be plausible evidence of a causal relationship between the process of environmental degradation and the loss of characteristic native biota of the ecological community.
**Table 15.** Corresponding thresholds of environmental degradation for the BC Regulation 2017 Clause 4.11 and the Bland *et al.* (2017) Red List for Ecosystems criteria. Thresholds of environmental degradation may be interpreted under C1, C2a and C2b (Bland *et al.* 2017) if reductions are over the past 50 years, the next 50 years, or any 50 year period including the past, present and future. Thresholds of environmental degradation should be interpreted under C3 (Bland *et al.* 2017) where the reduction is historical reduction since 1750.

Bland *et al.* (2017) present a range of abiotic variables that may be associated with environmental degradation. These include (but are not limited to): desertification of Rangelands; eutrophication of soils, freshwater streams or lakes; dehumidification of cloud forests; deforestation by acid rain; changed water regime or hydroperiod; salinisation of soils or wetlands; sedimentation of streams; sea level rise. Other possible factors may include changes to disturbance regimes upon which ecological communities depend (e.g. fire, water, storm).

**4.6.2 Disruption of biotic processes or interactions**

To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, an ecological community must have undergone or is likely to undergo within a time span appropriate to the life cycle and habitat characteristics of its component species a very large disruption of biotic processes or interactions (Subclause 4.12a), a large disruption of biotic processes or interactions (Subclause 4.12b) or a moderate disruption of biotic processes or interactions (Subclause 4.12c).
Disruptions of biotic processes or interactions are key symptoms of extinction risk for ecological communities (Rodriguez et al. 2007; Nicholson et al. 2009, Keith et al. 2013). Ecological communities that have undergone large disruptions of biotic processes or interactions, or are likely to undergo large disruptions in the future, are generally exposed to greater risks of extinction than those that have undergone or are likely to undergo smaller disruptions, or unlikely to undergo any disruption. Furthermore, a significant disruption of biotic processes or interactions almost certainly entails a significant loss of diversity in the community, as any assemblage embodies interactions and dependencies between its component species. Clause 4.12 specifies varying levels of disruption as eligibility criteria for listing in respective categories of threat. To be eligible for listing under Clause 4.12, communities that have undergone a sufficiently large disruption of biotic processes or interactions within the relevant past time frame need not exhibit evidence of a continuing decline in function. Furthermore, to be eligible for listing under Clause 4.12 the magnitude of these disruptions must be non-trivial, as outlined for declines in geographic distribution resulting from the action of threatening processes in Clause 4.10.

Thresholds of disruptions of biotic processes or interactions may be interpreted under D1, D2a and D2b (Bland et al. 2017) if reductions are over the past 50 years, the next 50 years, or any 50 year period including the past, present and future (Table 16). Thresholds of disruptions of biotic processes or interactions should be interpreted under D3 (Bland et al. 2017) where the reduction is historical reduction since 1750. The corresponding listing criteria (Bland et al. 2017) are a matrix of both severity and extent and to meet the thresholds these two components should meet the quantitative threshold. Relative severity is the estimated magnitude of past or future disruptions of biotic processes or interactions, expressed as a percentage relative to a change large enough to cause ecosystem collapse. Note that there must be plausible evidence of a causal relationship between the process of disruptions of biotic processes or interactions and the loss of characteristic native biota of the ecological community.
Table 16. Corresponding thresholds of disruptions of biotic processes or interactions for the BC Regulation 2017 Clause 4.12 and the Bland et al. (2017) Red List for Ecosystems criteria. Thresholds of environmental degradation may be interpreted under D1, D2a and D2b (Bland et al. 2017) if reductions are over the past 50 years, the next 50 years, or any 50 year period including the past, present and future. Thresholds of environmental degradation should be interpreted under D3 (Bland et al. 2017) where the reduction is historical reduction since 1750.

Table 17 gives examples of parameters representing both environmental degradation and disruption of biotic processes and interactions from current Determinations under the BC Act (Nicholson et al. 2009).

Disruptions of biotic processes or interactions (as opposed to reduction in distribution) of ecological communities is a very real threat to biodiversity, although it remains difficult to incorporate quantitatively in assessment protocols (Nicholson et al. 2009), but see Keith et al. (2013) for recent attempts to do this. Disruptions of biotic processes or interactions should be interpreted by considering specific types and symptoms of degradation that are based in ecological theory. Because every type of degradation or disruption of biotic process or interaction for each community cannot be listed as a sub-criterion with quantitative thresholds, these sub-criteria will inevitably be incomplete proxies of biotic processes or interaction, and composition. They therefore remain to some extent reliant on expert judgment (see Table 17 for examples from listings under the NSW BC Act).
A useful starting framework for assessing disruptions of biotic processes or interactions is provided by NatureServe’s method (Faber-Langendoen et al. 2007; Master et al. 2007) for characterising direct threats to species and communities, based on severity (degree of degradation), immediacy (time frame), and scope (spatial extent). It demonstrates how semi-quantitative and qualitative criteria can be set in a rigorous and transparent structure, especially when guided by examples. Nicholson et al. (2009), for example, suggest that communities could be classified as critically endangered if the decline in function is of high severity and scope, or as endangered if the decline in function is of high severity and at least moderate scope, or of moderate severity and high scope, etc. Similarly, Keith et al. 2013 provide examples of how disruptions of biotic processes or interactions may be quantified both in terms of severity and spatial extent of impact.

Setting robust quantitative thresholds for scope, severity and immediacy will require a substantial research effort, and in the interim, assessments will rely upon relative evaluations against examples. While scope and immediacy imply readily quantifiable parameters (e.g. proportion of the total distribution, time span over which reduction takes place, etc.), severity is more complex, although quantification may be feasible in many cases. For example, several quantitative parameters already exist for fragmentation (e.g. Rodriguez et al. 2007; McGarigal 2002). Table 17 gives examples of parameters representing both environmental degradation and disruption of biotic processes and interactions from current Determinations under the BC Act (Nicholson et al. 2009).

4.7 Clause 4.13 Quantitative analysis of probability of collapse of ecological community

To be eligible for listing as Critically Endangered, Endangered or Vulnerable, respectively, under clause 4.13, the estimated* (see Box 2) probability of collapse of the ecological community must be extremely high (Subclause 4.13a), very high (Subclause 4.13b) or high (Subclause 4.13c). The corresponding listing criteria in Bland et al. (2017) provide indicative guidance for quantitative interpretation of these terms (Table 18). The probability of ecological community collapse can be estimated with stochastic simulation models incorporating key ecosystem processes. A guide to quantifying collapse probability can be found in Bland et al. (2017).

Table 18. Corresponding thresholds for assessing quantified probability of collapse of ecological community under the BC Regulation 2017 and the Bland et al. (2017) Red List criteria.

5 Dealing with uncertainty

The listing criteria should be applied on the basis of available evidence (IUCN 2001). Inevitably, some aspects of this evidence will be uncertain to varying degrees, but this will not necessarily preclude species, populations or ecological communities from being assessed against the listing criteria. Absence of high-quality data should not deter attempts to apply the criteria (IUCN 2001). Given scarcity of data in many cases, it is appropriate to use the information that is available to make intelligent inferences about the assessment criteria, and hence the overall status of a species, population or ecological community. Inherent uncertainties have been recognised by Courts dealing with BC Act matters and are taken into account in Court decisions (Section 4.2, Keith 2009). The following sections provide guidance to identify sources of uncertainty, reduce it where possible, and deal with it explicitly in the listing process.

5.1.1 Sources of uncertainty

Uncertainty is an inherent and pervasive characteristic of all knowledge (Keith 2009). Regan et al. (2002) proposed a taxonomy that divided all forms of uncertainty into two groupings: epistemic and linguistic. Épistemic uncertainty encompasses imperfect knowledge about the state of a system – there is a fact of the matter, but it is unknown. Epistemic uncertainty is generally reducible by improving knowledge of a system. The most obvious and measurable sources of epistemic uncertainty arise from extrapolations or interpolations, limitations on sample data and variability of the system over space and time. Estimates of population size are usually subject to these sources of uncertainty. Another example is the species composition of an assemblage, which can be based only on a sample of all occurrences at all times and places, and is subject to both measurement error and natural variation (Regan et al. 2002; Elith et al. 2003).
Knowledge of species composition is also subject to systematic error because some of the component species are less detectable than others. The species composition of a community may appear to be more certain than it actually is unless its true variability is revealed by sampling at multiple times and places. Such data are rarely available (see Keith 2009 for an example). Consequently, the limitations concerning community description, and potential for undocumented variations need to be reported as transparently as possible.

Subjective judgement comes into play with any interpretation of data and this form of uncertainty is especially influential when data are scarce (Elith et al. 2003). For example, judgement may be applied to a limited set of field observations to compile a list of species that characterise a community throughout its occurrence or to identify processes likely to threaten the persistence of a community under given conditions. Other examples include inferences drawn about the overall rate of decline in a species, when only a few populations have been sampled. Uncertainty stems from the fact that trends over the observed populations and time frames may not represent the combined trend across all populations and the full-time frame required for assessment. This sort of uncertainty can be reduced with improved size and selection (stratification) of samples. Even where inference and estimation are made less subjective by statistical methods, expert judgements of some sort are sometimes essential to the application of listing criteria. Where this is the case, different experts may make different judgements and many exhibit serial over-confidence about their areas of expertise (Burgman 2005). In such cases a range of methods exist for eliciting and synthesising information from experts (e.g. the Delphi process - see MacMillan & Marshall 2006 and references therein). Key elements of sound elicitation include seeking multiple independent opinions (cf. consensus methods), appropriate weighting of different experts, corroboration with independent evidence, and examining the sensitivity of listing decisions to alternative advice.

A less obvious source of epistemic uncertainty arises from limitations on knowledge about the structure and mechanics of the system itself - model uncertainty. This relates to the definition of a species, population or community, its underlying theory and how these concepts apply to particular cases (Keith 2009). For example, the discrete and continuum models of communities may imply radically different interpretations as to whether particular species and locations fall within the circumscription of any given community (see Section 4.1.2 and Box 6). Since the concepts underlying models are described in language, they may also be prey to linguistic uncertainty.

Linguistic uncertainty arises from limitations imposed by incomplete, imprecise or inaccurate language and concepts (Regan et al. 2002). It may interact with epistemic sources of uncertainty, particularly model uncertainty. An important source of linguistic uncertainty arises when categorical language is used to describe entities that exist along a continuum from one state to another, e.g. wet vs. dry, hot vs. cold (Regan et al. 2002). This inevitably creates intermediate cases, which cannot be assigned with certainty to one category or another (i.e. there is no fact of the matter). This source of uncertainty, termed ‘vagueness’ (Regan et al. 2002), is present in both discrete and continuum models of communities, though is more explicitly recognised in the latter (Elith et al. 2003). Unlike, epistemic uncertainty, many forms of linguistic uncertainty cannot be reduced by collecting more information. Both Regan et al. (2002) and Elith et al. (2003) point out that vagueness cannot be eliminated simply by adopting sharper and sharper
boundary specifications. The adoption of arbitrary sharp thresholds to delimit communities from one another not only submerges the existence of a continuous reality, but sacrifices generality necessary for valid interpretation of the entities on the continuum. This has important implications for regulatory applications (see Keith 2009).

Some other forms of linguistic uncertainty, such as context-dependence, underspecificity and ambiguity (where one term has more than one meaning), also involve trade-offs between more explicit knowledge and necessary generality about the properties of any given species or community, as well as wide application of biological concepts and ideas (Regan et al. 2002). For example, when a species or community is described only as occurring in coastal Australia, there is no information about which parts of the coast its distribution includes or how far inland the ‘coast’ might extend. However, this level of underspecificity about its distribution might be appropriate if the species or community could occur within some coastal areas from which it has not yet been recorded. Some level of underspecificity allows necessary generality to accommodate unobserved cases (Keith 2009). Note that there are also issues of vagueness and ambiguity surrounding the interpretation of ‘coastal’ in this example. Similar issues arise when terms or concepts are subject to context dependence - what appears to be a reduction in one population may be viewed as a fluctuation when more populations and longer time scales are considered.

5.1.2 Dealing with uncertainty in decision-making

All decisions and their outcomes pertaining to the listing of species and communities will be influenced by uncertainty, whether it is explicitly recognised or not. There are essentially two complementary ways of dealing with uncertainty in the interpretation of ecological communities. First, the magnitude of uncertainty may be reduced, for example, by obtaining more information. This may involve consulting a wider or more balanced set of experts, undertaking more stringent evaluation of their opinions, and/or measuring characteristics such as composition, population trends and distribution more precisely with better sampling methods and more sampling effort. Quantitative descriptive methods such as species fidelity measures (Bruelheide 2000, Tozer 2003) also help reduce uncertainties about community properties. This has benefits, irrespective of whether decision-making is deterministic or risk-based. However, many forms of uncertainty, such as model uncertainty and most linguistic uncertainty, are more difficult to quantify and reduce. Linguistic uncertainty could potentially be reduced by use of more precisely defined terms, but these rely on other terms, which in turn rely on others. As noted above, there also comes a point where terms become defined so tightly that they lose generality and fail to meet their original intent (Regan et al. 2002).

A second means of dealing with uncertainty is to explicitly incorporate what we know about it into the assessment process. A wide range of risk-assessment methods and decision-theory tools have been developed for this purpose (Possingham et al. 2000; Ben Haim 2001; Burgman 2005; Moilanen et al. 2005). Some of these tools are complex and their uptake into conservation planning practice has been slow. However, the principles underlying them are simple: (i) questions are considered from a probabilistic perspective (quantifying uncertainty) rather than a deterministic one
(ignoring uncertainty); and (ii) listing decisions aim to be robust by reducing the risk of ‘bad’ outcomes as defined by the listing objectives.

Rather than ask deterministically whether a nominated species or community has been reduced below a threshold fraction of its prior distribution, in probabilistic language the initial question becomes, ‘how likely is it that the nominated community has undergone a particular level of reduction?’ The estimation of likelihood then requires relevant sources of uncertainty to be evaluated and any estimates of reduction to be quantified with both a best estimate (most likely value) and an estimate of uncertainty about the best estimate.

Elith et al. (2003) suggest a variety of methods for reducing and quantifying each type of uncertainty. IUCN (2017, section 4.5.3) gives extensive guidance for the treatment of uncertainty for estimating population reduction. Uncertainty may be expressed as statistical probabilities if quantitative data are available. Otherwise, it will rely on expert elicitation and judgement to express subjective probabilities or ‘degrees of belief’ about alternative states of a system or alternative values of a quantity within plausible bounds (Kyburg & Smokler 1964; Burgman 2005). The simplest method for characterising uncertainty with subjective probabilities is to estimate upper and lower bounds, which represent the plausible range around the best estimate. Examples for a variety of parameters are given in Box 11.

If experts are able to estimate the most likely state of a system or best estimate of a quantity, they should also be able to provide information on the uncertainty associated with their advice (e.g. as degree of belief and/or plausible bounds). This second piece of information is often overlooked, but must be elicited from relevant sources (data sets, published reports, experts, etc.) to ensure that listing decisions adequately incorporate uncertainty in the best available knowledge.

To that end, the range of values (best estimate, upper and lower bounds) can each be propagated through the assessment to evaluate the sensitivity of the assessment outcome to uncertainty in parameter estimates. The simplest method is by interval arithmetic, though other more sophisticated methods are available (e.g. fuzzy arithmetic; Akçakaya et al. 2000). Where the assessment outcome is relatively insensitive to uncertainty, it will produce a single category of threat (e.g. EN). In other cases, the bounded estimates may result in a range of plausible threat categories (e.g. EN-VU), and the Committee will need to decide on a category for listing, given an appropriate attitude to the uncertainty. These attitudes may vary from precautionary (assigning a higher category of threat within the plausible range) to evidentiary (assigning a lower category of threat from within the plausible range), depending on the circumstances and consequences. IUCN (2001, 2017) recommend a ‘precautionary but realistic’ attitude to uncertainty in listing decisions.

**Box 11. Examples of deriving bounded estimates from uncertain information on listing parameters**

**Estimating the number of mature individuals**

*Callitris endlicheri* – Many plants are either too small or too numerous to count reliably and/or in a timely manner over large areas. Mackenzie & Keith (2009) estimated the number of seedlings in a population from samples of seedling density. The best estimate
was obtained by multiplying the mean density by the area occupied by the population. Confidence intervals representing upper and lower bounds were calculated from the variance in density scaled by the proportion of the total population that was sampled (see Keith 2000 and Mackenzie & Keith 2009 for relevant equations).

*Cynachum elegans* – The available information on population status often varies within a species. This species comprises a large number of populations (c. 90), of which 40% were surveyed in detail, producing high-precision population estimates, while others were recorded only with cursory observations and no estimate of population size. Scott (2009) calculated the mean and standard deviation of population sizes (13 ± 5) from the surveyed subset of populations to draw inferences about the likely sizes of unsurveyed populations. A best estimate of the total population size (1170 plants) was calculated by multiplying the mean population size by the total number of populations. Upper and lower bounds (720-1620) were calculated from the 90% confidence intervals. The bounded estimate was well within the Endangered threshold (2500 mature individuals) under Clause 4.4 of the listing criteria, suggesting that the status is unlikely to change, even if a number of previously unrecorded populations are discovered.

**Estimating the area of occupancy**

*Genoplesium baueri* – Species locality records commonly extend back to the nineteenth century. In some cases, a species may not have been recently recorded from locations where historical records exist. This may be due to extirpation of the population or because the species has eluded detection. Consequently, the records represent some populations that are certainly extant, some that are almost certainly extinct (e.g. long undetected and habitat destroyed) and some whose status is uncertain (e.g. no recent records, but habitat remains intact). Detectability may be low for inconspicuous plants such as orchids. Copeland (2008) compiled 25 records on *G. baueri*, of which 17-19 were considered likely by experts to represent extant populations. He estimated that the area of occupancy was 64-72 km², depending on whether the uncertain populations were considered extant.

*Sandhill Pine Woodland* – Where vegetation mapping studies exist, the assignment of map units to a nominated ecological community can be uncertain for a variety of reasons. Mackenzie and Keith (2007) identified candidate map units from several different mapping studies that may be part of Sandhill Pine Woodland. Some mapping studies suggested that the distribution of the community is more restricted than others. Calculations based on different combinations of map units indicate that the mapped extent of the community is likely to be between 50 000 ha and 120 000 ha.

**Estimating the proportional decline in population size or geographic distribution**

*Pseudophryne corroboree* (Southern Corroboree Frog) – Sources of uncertainty in estimation of animal populations include imperfect detectability and variability of numbers in space and time. Bray (2008) compiled data from Hunter et al. (2007) and Osborne et al. (1999) to estimate population trends from two different kinds of surveys: i) an extensive survey of 40 sites to record whether male frogs were calling during the breeding season; and ii) an intensive census of a large population to record the number of individual males calling during the breeding season. The number of sites with calling males declined by 89% and the number of calling males at the census site declined by 97% over a ten year period. Assuming that the population was either stable or declining (or even underwent a modest increase) prior to the 10-year survey period, the species is highly likely to have undergone a reduction of more than 80% over three generations (21 years) and hence qualifies for listing under Clause 4.2 of the listing criteria.
Coolibah – Black Box Woodland – Maps of ecological communities are inherently uncertain. Maps produced by different observers will differ to varying degrees for various reasons. Temporal comparisons of maps by different observers can compound these uncertainties. Keith *et al.* (2009) estimated the proportional decline in distribution of this community (since European settlement) using a set of vegetation maps that covered various portions of the community distribution. They calculated a best estimate of decline from maps identified as the most reliable and consistent throughout the distribution. They estimated a lower bound of decline by substituting maps that had the smallest historic distribution and largest contemporary distribution into the calculation. The upper bound was similarly calculated from the maps with the largest historic distribution and smallest contemporary distribution.
6 Acknowledgements

We wish to thank Dr David Keith for his considerable efforts in compiling the first edition of these Guidelines. Through his research expertise in ecological communities and his membership of the International Standards and Petitions Working Group of the IUCN, David brought considerable knowledge and invaluable insights to greatly assist the deliberations of the New South Wales Scientific Committee during his membership of the Committee.

We would also like to thank Dr Tony Auld who has revised and updated a number of earlier versions and the current version of the Guidelines to ensure they keep pace with changes and refinements made to the IUCN criteria. Tony has served two terms on the Committee and brought considerable expertise in IUCN based assessments of species and ecological communities to the Committee. His ongoing advice and assistance to the Committee is highly valued and appreciated by the Committee.

These guidelines will facilitate an improved understanding and objectivity in conservation assessment.
